The primary raw material sources of the monomers used to prepare commercial nylons have been listed in Table 2. Commentary on most monomer syntheses can be found in [5-7], [19]. The diamine for PA 46 is made via the addition of hydrogen cyanide to acrylonitrile [124]. For convenience, certain basic parameters of the commercial nylons have been assembled in Table 4.

Table 4. Basic parameters of commercial nylons

PA	CH_2/CONH [a]	M_u [b]	[CONH], $10^6/M_u$ [c]	T_m [d], °C	Density, g/cm^3
46	4	99.13	10 088	295	1.18

[a] Ratio of methylene to amide groups per repeating unit (or average monomer unit).
[b] M_u is the average molecular mass per amide group.
[c] [CONH] is the concentration of amide groups.
[d] The melting temperatures (points) are as determined by the disappearance of the last vestige of birefringence on a hot stage and correspond to the minimum fabricating temperature. Estimates were made where such data were not available.

5.1. PA 46

The 46-salt can be converted into prepolymer at 180 – 240 °C under steam pressure [122], [125]. SPP is carried out at 220 – 275 °C. Variations include a continuous polymerization method involving short exposure at 293 °C [125], water extraction of prepolymer to improve its color [126], a two-stage heat treatment to make prepolymer [127], control of temperature and steam pressure to yield high molecular mass [128], and polymerization with some of the adipic acid replaced by terephthalic acid to give a PA 46/4T copolymer [129].

5.2. PA 66

The first step is preparation of pure, balanced salt in aqueous solution. Stoichiometric equivalence is determined by pH measurement. Some excess diamine is normally added to compensate for losses due to its relative volatility. The equivalence pH for the aliphatic salts approximates 7.6 [130], [131]. Charcoal decolorization of the salt solution is required unless the diamine has been carefully refined and, in particular, is free of *cis*-1,2-diaminocyclohexane [132]. Purging a charcoal bed with inert gas increases its life [133]. Treatment with diacid followed by removal of acid with diamine before use with salt solution avoids initial losses in molecular mass [134]. A two-stage, recycling method of salt preparation is used in a continuous process [135]. Two-step addition to diamine with intermediate evaporation of water yields a concentrated salt solution [136]. Ways of mixing molten acid and diamine have been patented [137-139]. To avoid precipitation when stored at about 25 °C a 50% aqueous salt solution is normally prepared.

5.2.1. *Batch Production*

The stored salt solution is concentrated under pressure to 65 – 80 % before charging to an autoclave. A typical cycle is shown in Figure 8 [140]. The essential features are heating to 210 °C under autogeneous pressure to reach a pressure of 1.75 MPa, gradually increasing the temperature to about 275 °C while releasing steam at a rate which maintains the pressure, reducing the pressure at a rate that avoids cooling and finally holding the batch at atmospheric or reduced pressure to obtain the target molecular mass before extruding the polymer under inert gas pressure. This procedure is designed to assure that there is enough water present to avoid freezing of the batch before the melting point has been reached. Water also minimizes excessive loss of diamine. Stirred autoclaves are used but are normally unnecessary. The extrudate is a wide ribbon that is quenched with water that is subsequently removed by jet blowers. The ribbon is cut into chips which are blended and packaged [141], [142]. Hermetically sealed containers are used to avoid absorption of moisture that can hydrolyze polymers to lower molecular masses during subsequent melt processing. The containers vary from 10 kg bags to 500 kg or larger cartons. Nylon molders and extruders have drying equipment to contend with situations where the moisture content of as-received or reprocessed material requires adjustment.

5.2.2. *Continuous Production*

The same concerns for control of the rate of removal of water and loss of diamine exist as in batch polymerization, but the situation is complicated by the needs of a continuous process. Typically, a first stage involves evaporation/reaction with controlled loss of water to form a prepolymer and minimize loss of diamine (Fig. 9). Further reaction occurs in subsequent stages with controlled evaporation in devices known as “separators” and “flashers”. The desired molecular mass and water content are obtained in a “finisher”. A large patent literature exists that claims improvement in each of these devices or combinations thereof for process simplification (see the review [140]). An early process that includes an additive port for delusterant is shown in Figure 9 [143]. A modification thereof (Fig. 10) includes a separator after the flash tubes to provide an essentially steam-free melt to the finisher [144]. Further improvements include the addition of a cage structure at the top of the screw section for better flow and reduced gel formation [145], insertion of static mixers in the flash tubes [146], putting holes in the ribbon flight in the separator [147], and providing flow splitters in the flash tubes [148]. A modification between the flash tubes and the separator significantly increases steam release and achievable molecular mass [149]. Dimensions, time, temperature, and pressure vary somewhat with specific design, but the same basic needs outlined above always apply in order to obtain a molten, high molecular mass product of low water content that can be fed to spinners or granulators. Severe constraints such as holdup spots and exposure to oxygen must always be avoided in continuously operated, high-temperature equipment such as polymerizers, extruders, or injection molding machines.

Another design (Fig. 11) involves essentially adiabatic evaporation in a second zone by directing the flow from an initial

evaporator/reactor through a perforated ring nozzle against a heat exchanger with a surface of high thermal conductivity [150]. Another device emphasizing adiabatic evaporation makes use of the observation that the presence of low molecular mass polymer in salt solution decreases the tendency of the salt to precipitate [151], and another resorts to a multiplicity of zones [152]. Other procedures include rectification columns in the first zone, e.g., [153], [154]; a one-stage process with a long, narrow, coiled tube emptying into a stirred melt pool [155]; modified screw finishers [156-158]; designs to provide thin films of melt [159-161]; an apparatus that uses a dry salt charge [162]; and a dispersion technique for high-viscosity polymers involving cyclic monomers [163].

5.3. Other AABB Polyamides

The polymerizations yielding PA 69, PA 610 and PA 612 are subject to the same concerns as that yielding PA 66. These polyamides are made in much the same way with differences due to different melt viscosities and melting points. The choice between continuous or batch process depends mostly on production volume. Because of smaller sales volume, the batch method is favored for these specialty nylons.

The AABB principles described above can easily be extended to monomers containing an aromatic or cycloaliphatic moiety in the AA, the BB, or both portions of the molecule. Because of the presence of these structures these polyamides present special problems due in part to their high viscosity and/or stability at the high processing temperatures. An example is PA MXD6, a polyamide prepared from *m*-xylylenediamine (MXD) and adipic acid. Careful control of steam pressure in the early stage of polymerization of MXD6 is required to minimize decomposition of the aromatic diamine [164]. In the production of TMDT polymer, the salt is precipitated from an aqueous solution with isopropyl alcohol, partially condensed in a stirred reactor, and finally polymerized to a number-average molecular mass of about 20 000 in an extruder [165].

An emerging area of interest is in the polyphthalamides (PPAs), also known as high temperature nylons (HTNs). These are high melting semiaromatic nylons resulting from the addition of an aromatic ring to the polymer backbone. The high polymerization temperatures required for their manufacture necessitates either a short residence time in the melt by using and extruder or polymerization below their melting points (see Section Solid-Phase Polymerization) [166], [167].

5.4. PA 6

Continuous processes are used by the major manufacturers of PA 6. The so-called VK tube (Vereinfacht Kontinuierlich = simplified continuous) was developed in Germany. It is a vertical tube operated at atmospheric pressure wherein heating and prepolymerization take place in the upper part and polymer is formed in the lower section [168]. Problems of initial stoichiometry and ingredient volatilization, inherent with AABB polymerization as already discussed, do not apply; however, the need to free the product of its equilibrium content of monomer and oligomers presents a different kind of problem. A schematic of the BASF process [6] shows a VK tube feeding a pelletizer followed by a water extraction unit (Fig. 12). A process [169] involving vacuum extraction is shown in Figure 13. Claim is made that controlling initial conversion to 45 % yields a product with less than 2 % of cyclic oligomers with a vacuum finish that does not require prolonged heating at less than 665 Pa [170]. Improved processes include a baffled hydrolyzer operating in plug flow and at a carefully controlled temperature [171] and a two-stage hydrolyzer [172].

The simulation and optimization of the hydrolytic polymerization of caprolactam have been attempted [58], [173], [174]. Lack of detailed manufacturing data has been indicated to prevent confirmation of the analysis.

Polymerization in an extruder has also been discussed [175]. Numerous publications and patents continue to appear that deal with the anionic polymerization of caprolactam. No large-scale applications exist as yet although modified systems in reaction injection molding (RIM) for the production of block copolyesteramides and copolyetheramides have been

developed by several companies [35]. Some details on recommended RIM procedures such as separation of feed streams, mold design, and temperature have been published [176], [177].

5.5. PA 11

PA 11 is made in a continuous process that is operated under inert gas at atmospheric pressure [178]. The monomer (11-aminoundecanoic acid, which is made from castor beans) is suspended in water and mixed with the desired additives (antioxidants, etc.) before charging to a three-zone, upright converter. The monomer is melted, water eliminated, and the polymerization begun in the top section. Near completion of the condensation occurs in the middle zone. Adjustment to the target molecular mass takes place in the bottom section which provides a melt pool for uniform discharge of product. The good thermal stability of the polymer and the low tendency of the monomer for cyclization simplify the process design.

Phosphoric acid catalyzes the polymerization as does hypophosphoric acid. The latter can, however, insolubilize the product if used in excess with prolonged heating [179].

5.6. PA 12

Polylaurolactam, PA 12, is made by heating dodecanolactam (which is made from butadiene) with an acid catalyst such as phosphoric acid in the presence of water to effect conversion to a prepolymer, then evaporating the water, and finally heating in an inert atmosphere to complete the polymerization [35], [180]. Temperatures up to 350 °C may be used to effect completion [181], [182]. Confirmation of the independence of reaction rate on molecular mass and of a most probable molecular mass distribution together with an expression relating degree of polymerization to viscosity in *m*-cresol are provided in [183].

[Top of Page]

6. Properties

The enduring utility of nylons rests upon their combination of properties and upon their susceptibility to modification. Key properties are resistance to oils and solvents; toughness; fatigue and abrasion resistance; low friction and creep; high strength; stability at elevated temperatures; fire resistance; drawability; good appearance; and good processibility.

Polyamides are readily modified in order to achieve desired changes in processing behavior or properties. This characteristic has allowed them to sustain their growth in spite of the advent of challenging new materials. However, modifications to enhance some specific properties can have negative effects on other properties. Basic modifications can be accomplished through changes in the polymer molecule itself and/or the incorporation of additives. Alternative techniques of modification include use of branching agents (see Section Control of Rheological Properties.) and post-polymerization treatments such as annealing, conditioning to a specific moisture level, dyeing, metallizing, painting, irradiation, or chemical reaction such as alkoxyalkylation.

6.1. Properties of Unmodified Polyamides

A problem common to most polymers is the lack of adequate and comparable data. Nylons are no exception; however, the increasing global acceptance of ISO protocols in measuring properties has alleviated the situation. A limited comparison of unmodified nylon resins is provided in Table 6. Even these data are not unambiguous because the molecular masses are not specified. The table is self-evident and reflects the differences in amide group concentration and crystallinity. Information on literally hundreds of nylon compositions can be obtained from various web sites maintained by the suppliers and in the Campus database [184]. Additional information is also available from the *Plastics Technology Handbook* and *Modern Plastics Encyclopedia*, which are both issued annually.

This introductory section, however, is concerned with those features of neat polyamides that determine their properties and account for differences between individual nylons. The most distinguishing feature is the amide group, which is responsible for strong hydrogen bonding between adjacent chains. Melting point increases with increasing ratio of CONH groups to CH_2 groups in the chain and the increased opportunity for hydrogen bonding, but not regularly because whether the number of CH_2 groups between the CONH groups is odd or even is important as well as the ratio of CH_2 to CONH. The odd number of CH_2 groups between the amide groups in PA 6 allows complete hydrogen bonding when the amides in adjacent chains have an opposed or antiparallel orientation but not when they have the same or parallel orientation (Fig. 14). Changing from a parallel to an antiparallel array requires inverting the entire molecular chain in this odd-numbered case, but only a one-segment lateral movement is needed if there is an even number of CH_2 groups, as in the case of PA 66 with its intervening number of 4 and 6 CH_2 groups. It is believed that this odd/even feature accounts for the lower melting point and percent crystallinity of PA 6 versus PA 66. It is the reason in general why PA-odd and PA-odd/even have lower melting points than comparable or similar PA-even/even, such as PA 6 versus PA 7.

Figure 14. Schematic of a hydrogen bonded sheet of PA 6 with antiparallel (A) and parallel (B) orientation of amide groups

Increasing crystallinity results in higher stiffness, density, tensile and yield stress, chemical and abrasion resistance, and

better dimensional stability. It decreases elongation, impact resistance, thermal expansion, and permeability. Crystallinity is responsible for the development of microscopically observable structures, known as spherulites, that scatter light and make nylons opalescent unless very thin. The transparent nylons are amorphous and are made so by appropriate copolymerization involving at least in part aromatic or cycloaliphatic AB, AA, or BB monomers in order to have acceptable stiffness.

Orientation [5, p. 300] contributes importantly to properties not only in film, fiber, and strapping but also in injection-molded articles. The resulting anisotropy means that properties vary with the direction of stress and must be considered in rationalizing resin behavior.

Water absorption is characteristic of nylons. Unless compensated for by increased crystallinity, a higher proportion of amide groups leads to higher water adsorption. Increased water content has an effect analogous to that of increased temperature, i.e., enhanced segmental mobility with, for example, concomitant loss in stiffness and tensile strength, gain in toughness, and growth in dimensions (elongation). At very low temperatures, however, water stiffens the nylon. Thus, the brittleness temperature (ASTM D 746) of PA 66 is – 80 °C if dry and – 65 °C if conditioned to 50 % relative humidity. Properties are frequently reported in the “dry”, as-molded, condition corresponding to about 0.2 % water or less, and after equilibration to a specified relative humidity such as 50 or 65 %, and occasionally to 100 %. The greatest change occurs in the vicinity of the glass transition temperature (T_g) so that a useful aid in understanding behavior is a knowledge of the effect of humidity on T_g. This is complicated because of variation with the method of calculation or measurement (Table 5), but it is generally true that nylons with fewer CONH groups and lower water adsorption have a lower dry T_g but show less change of T_g with relative humidity [19], [121], [185-190].

* Data assembled from publications of various manufacturers for standard injection molding grades. Variations in molecular mass contribute to differences in properties.

Little change in sensitivity to aliphatic hydrocarbons occurs with a change in polyamide type, but aromatic hydrocarbons are more strongly absorbed by polyamides with fewer amide groups. For example, PA 66 and PA 6 absorb 1 % toluene; PA 610, PA 3, and PA 11 absorb 6.8 %.

With this background now in place, a comparison of the properties of various nylons can be made, moving from the least aliphatic, to the most aliphatic, and then to semiaromatic nylons.

PA 46 is structurally similar to PA 66, and is produced from 1,4-diaminobutane and adipic acid. This nylon has the highest amide-to-methylene group ratio and the highest crystallinity of the commercial nylons. The high amide concentration accounts for the high moisture absorption of the polymer. Its melting point is 290 °C.

PA 66, which has one amide group for every 4 or 6 (with an average of 5) methylenes, has a high melting point of 269 °C, good strength and creep resistance, and excellent gas barrier properties. These qualities have led to its widespread use in automotive mechanical and electrical and electronic applications.

PA 6 also has an amide to methylene ratio of 1:5, but the odd number of methylene units retards crystallization and results in a more amorphous polymer with a lower melting point of 228 °C. These characteristics can be desirable for extruded film and wire and cable jacketing, but make PA 6 somewhat more sensitive to moisture and chemicals and limits its resistance to temperature spikes.

PA 69, 610 and 612 are all produced from hexamethylenediamine plus azelaic, sebacic, or dodecanedioic acids, respectively. PA 612 is intermediate between 6/66 and 11/12 with an average amide to methylene group ratio of 1 : 8, and provides an excellent compromise between PA 66 and higher nylons, with its excellent dimensional stability, reasonably high melting point (212 °C), strength, creep resistance, and barrier properties. This balance leads to widespread use in toothbrush filaments, battery components, and parts that are exposed to hot aqueous environments.

Higher nylons, like PA 11 and 12, have much lower amide to methylene group ratios (1:10 and 1:11 respectively), which results in more polyethylene-like materials that have excellent dimensional stability, low-temperature toughness, and stress-crack resistance at the expense of lower melting point and strength. They are readily plasticized for use in flexible, chemically-resistant tubing that has high burst pressures. The long aliphatic chains impart a low affinity for moisture. In addition, PA 11 is available in powder grades that may be applied by electrostatic spray or in fluidized beds for coating metallic parts.

Semiaromatic nylons are generally copolymers that are commonly made using terephthalic acid and/or isophthalic acid as comonomers often with an aliphatic or alicyclic acid. Common semiaromatic nylons will contain units derived from hexamethylenediamine and adipic acid or caprolactam. They typically have high melting points (295–325 °C for commercial grades) and exhibit a significant decrease in moisture absorption when compared to purely aliphatic nylons. The aromatic groups in the polymer backbone make them less mobile than linear aliphatic nylons and contribute to their high stiffness and good strength, creep resistance, and dimensional stability. Biaxially oriented films made from semiaromatic polymers provide excellent gas and oxygen barrier properties allowing for use in packaging materials and bottles.

Control of Rheological Properties. Control of melt rheology is very important for nylon processing (see Chap. Processing). Low viscosity is desired for molding application for easy mold-filling. On the other hand, a high viscosity and melt strength are desired in extrusion and blow-molding applications. Control of molecular mass is the most convenient method for controlling rheological properties. Most polyamides have number-average molecular masses in the range of 11 000 to 34 000. Toughness increases with increasing molecular mass, but the effect is a moderate one. The major practical reason to change the molecular mass of a polyamide is to obtain a desired level of melt viscosity, which can range from less than 1000 Pa · s for injection molding to over 4000 Pa · s for shaped extrusion.

Another technique used to modify rheological properties is to change the molecular architecture. Introduction of low-level branching results in more non-Newtonian behavior, especially at low shear rates where an increase in melt strength and melt viscosity is obtained. Star nylons (see Section Molecular Mass), although known for a number of years, are a new class of commercially available semicrystalline polyamides that exhibit a quasi-Newtonian rheological behavior and

enhanced flow properties during processing [191]. The polymer is a modified PA 6 and has a star-like structure that is based on proprietary polymerization techniques. Polymerization catalysts and chemicals incorporated into the polymerization cycle produce a nylon with controlled branches. These materials can be compounded with large amounts of glass fibers or mineral fillers and molded with increased melt flow under normal processing conditions. The enhanced flow characteristics promote an excellent surface finish and aesthetic appearance. Commercial uses now include automotive engine covers, air-intake manifolds and trim parts, fishing reels, and appliance doors [192].

6.2. Copolymerization

Copolymerization to modify the properties of polyamides has long been practiced. This technique allows one to obtain varied properties without resorting to developing new polyamides from new monomers. Copolymerization increases the disorder in the polymer molecules and interferes with the ability of the molecules to pack and form hydrogen bonds. As a consequence, copolymers in general are characterized by a lower degree of crystallinity and a slower rate of crystallization, greater transparency, a lower modulus and strength, and greater solubility than the respective homopolymers. In a PA 66/6 copolyamide, for example, the melting point minimum is about 180 °C at 40 wt % of caprolactam units. PA 66/6 copolymers with about 40–65 wt % caprolactam units become soluble in hot methanol whereas the homopolymers PA 6 and PA 66 are insoluble in this solvent [19], [193], [194]. Terpolymers such as PA 66/6/610 are designed to further enhance solubility for use as binders [19], [195]. Transparency with good retention of properties is achieved by use of alicyclic or aromatic comonomers as has been noted for PA TMDT. A review of transparent polyamides that includes a comparison with other transparent engineering plastics is given in [196], [11, pp. 377–387].

There are quite a number of pairs of monomers, however, that have comparable distances between their functional groups and that yield copolymers in which the amide moieties can assume the proper orientation for hydrogen bonding. These molecular characteristics permit the comonomers to crystallize in the same morphology [197-199]. Instead of being depressed, the melting points of these isomorphous copolymers are weighted averages of the melting points of the component homopolymers. Some examples of isomorphous pairs of monomers are adipic and terephthalic acids; *p*-benzenedipropionic and sebacic acids; and *p*-xylylenediamine and *m*-xylylenediamine. For a more extensive discussion refer to [[11], pp. 370–372].

6.3. Modification by Additives

Additives are materials used in small amounts (less than 5 wt % and usually less than 1 wt %) to affect various aspects of polymer processing, polymer properties, and/or appearance. Additives used to alter properties or appearance include antioxidants, antistatic agents, biodegradative agents, biopreservatives, blowing agents, colorants, fragrances, and stabilizers against hydrolysis, thermal degradation, or UV degradation. Processing additives include coloration inhibitors, lubricants, mold-release agents, nucleating agents, and viscosity thickeners or reducers. They have little effect on the physical properties except in the instance of nucleating agents, which not only increase the rate of crystallization and the degree of crystallinity, but impart reduced mold shrinkage and increased tensile and flexural properties. Enhanced crystallization may be desired to shorten molding cycles, and also to modify mechanical properties.

Modifiers are used in larger amounts, usually more than 5 wt %, in order to achieve desired changes in properties. Modifiers include mineral fillers, glass or carbon fibers, lubricants to improve wear and friction, plasticizers, fire retardants, electrically conductive materials, and/or blends with other polymers to toughen or otherwise affect the nylon. A broad discussion of additives is given in [11, pp. 361–448], [200].

6.3.1. *Filled and Reinforced Polyamides*

Fillers and reinforcing agents have contributed significantly to the sustained growth in the use of nylons. Particulate mineral fillers (e.g., aluminum or calcium silicates) always increase the modulus of elasticity and often the tensile strength whereas elongation always decreases. Impact strength as measured by the notched Izod test may or may not improve; it depends on the choice of filler and matrix. Temperature resistance is increased.

Reinforcement with glass and carbon fibers has similar but larger effects with consistently improved Izod impact strengths because of the fiber acicularity. Warpage can be a factor in some applications. This again relates to fiber acicularity and is, accordingly, less in the typical mineral-filled compositions. Mixtures of fillers and reinforcing agents are used, therefore, to cope with such situations. Important factors are the efficacy of the bonding agent used to promote adhesion between the filler or the reinforcing agent and the polyamide matrix and the length to diameter ratio of the fiber in the final product. The properties in Table 7 were chosen to illustrate these effects but because of the number of variables involved they should not be construed as limiting.

Table 7. Selected properties of dry, filled/reinforced PA 66 [*]

** "Mineral" as found in the nylon literature normally refers to various silicates and carbonates.

Long glass fibers are used in polyamide compositions with the attendant implications for properties and processing [201], [202]. Most of these compositions are produced by a pultrusion process [203], [204]. The continuous glass fibers are pulled through an impregnation line where they are coated with nylon resin. Upon cooling, the resin is chopped into long pellets that contain reinforcing fibers equal in length to the pellet. Traditional extrusion compounding of glass into nylon yields much shorter fibers, and hence less stiffness and worse transverse mechanical properties. The balance of properties makes long-fiber reinforced compositions ideal for the replacement of metals such as die-cast aluminum in many parts. In specialty applications, long fibers of carbon, aramids, and steel are used in addition to glass [205].

Nanocomposites are emerging with increased acceptance of the properties that they offer. They can improve strength, stiffness, heat deflection temperature, dimensional stability, gas barrier, flame retardancy, and electrical conductivity. Nanoparticle platelets are only 1 nm thick with an aspect ratio (*L/D*) sufficiently high that relatively low loadings (generally 2 to 6 wt %) provide significant property advantages. These clay-based additives have been used with PA 6, PA 612, and PA MXD 6 to improve stiffness heat resistance, oxygen barrier and gloss, but confer a disproportional loss of toughness. In 2000 these nylon compositions were first commercialized for container and packaging applications [206-208]. A more detailed discussion of the many aspects of nanotechnology is given in [209].

6.3.2. *Blends and Alloys*

Blends of nylon (and polymers in general) are mixtures that contain at least one other polymer or copolymer. The properties of the blends can be additive, averaged, synergistic, or antagonistic. An alloy is an immiscible polymer blend having a modified interface between both components and/or morphology. While positive synergism of the components is most desired, a weighted averaging of properties based on the volume component of resins is usually the rule. Nature rarely provides something for nothing so there are often tradeoffs of properties and for every advantage obtained by a resin blend, there are often disadvantages as well. The disadvantages are often so significant that the resulting material is unusable. The primary reason for the negative results is that most polymer pairs are immiscible because of high interfacial tension, which results in phase-separated components. A brief list of some common property tradeoffs is:

Stiffness, strength (e.g., glass, mineral)	vs. toughness, ductility
Melt flow	vs. toughness, elongation
Fire retardance	vs. environmental considerations, toughness, melt stability
Solvent resistance (i.e. crystallinity)	vs. mold shrinkage
Cycle time	vs. shrinkage
Softness	vs. creep, stiffness
Product complexity	vs. compounding yield, speed, cost

The successful use of blending to tailor-make materials for specific end use applications depends on the type of resins used, their morphologies, the relative levels of the resins, and the property tradeoffs that are acceptable [210-212].

Some of the polymers, that have been successfully blended with polyamides include polypropylene (PP), high impact polystyrene (HIPS), styrene-acrylonitrile (SAN) and acrylonitrile-butadiene- styrene (ABS) copolymers, poly(methyl methacrylate) (PMMA), styrene- maleic anhydride (SMA) copolymer, EPDM elastomers, polycarbonate (PC), and poly (phenylene ether) (PPE) [213].

For all blends, it is essential to develop processes that control the morphology and the interfaces of the phase-separated components. Interfaces can be modified by the addition of reactive and nonreactive compatiblizers, as well as by reactive extrusion to assure a controlled chemical reaction between the components and thus compatibilize the blend in situ [214].

The broad utility of nylons was restricted for many years by their notch sensitivity and loss of toughness at very low temperatures. For example, the impact strength of PA 66 at 23 °C and 50 % humidity is 37 J/m with a notch radius of 0.05 mm, 112 J/m with a 0.25 mm radius (the Izod specification of ASTM D 256), and 366 J/m with a 0.75 mm radius. At –40 °C with the standard radius of 0.25 mm, it is 27 J/m. Some improvements were made, but no major breakthrough occurred until suitably defined elastomeric modifiers were used [215]. This work yielded compositions that were ductile and exhibited Izod impact strengths over 534 J/m even when dry. Independence of notch radius down to 0.0025 mm; insensitivity to part thickness, orientation, proximity to the molding gate or rate of loading; and improvement down to about –20 °C were demonstrated [216]. One requirement in this work was a sufficiently small particle size of the dispersed elastomeric phase. Ductile behavior independent of part thickness has been shown for a PA 6–ABS blend (about 50/50 weight ratio) with a cocontinuous phase morphology [217]. Another variant of toughener involves a core – shell structure in the dispersed phase [218]. The effect of orientation, position in the molded part, rate of loading and temperature has not yet been shown for these alternative materials. Many studies on toughening nylons from both industrial laboratories and

academia have appeared. Morphology, type of toughener, testing with sophisticated instrumentation, and analysis of the mechanism of toughening have been studied. It is, however, beyond the scope of this report to delve into this broad and complex subject.

The number of impacts to failure of toughened PA 66 increases, as would be expected, as the impact energy is lowered below that required for failure in a single blow [219]. Noteworthy, however, is the resistance to repeated impact of neat PA 66 [219], [220].

Mineral-filled and glass-reinforced nylons have also been toughened. For example, a dry, mineral-filled product with a tensile strength (TS) of 89 MPa, a flexural modulus (FM) of 5300 MPa, and a notched Izod impact strength (Iz) of 69 J/m was toughened to yield one with corresponding values of 79 MPa, 4600 MPa, and 130 J/m [221]. Similarly, a dry, glass-reinforced PA 66 with a TS of 200 MPa, a FM of 8960 MPa, and an Iz of 100 J/m was toughened to yield a TS of 140 MPa, a FM of 7000 MPa and an Iz of 250 J/m [221]. These examples illustrate the feasability of the wide spread practice combining various additives and modifiers to meet the demands of specific applications.

6.3.3. *Flame-Retardant Polyamides*

Many nylons are rated UL 94 V-2, and fire-retardant grades with a UL 94 rating of V-0 in thin sections are available. For a discussion of UL ratings, see ⟶. Common flame retardants are highly-halogenated organic compounds and polymers such as brominated polystyrenes, poly(dibromostyrenes), or dechlorane [222], [223]. These are often used in combination with a synergist such as an antimony oxide. Red phosphorus is also used as a flame retardant [224]. Concerns about the toxic fumes released when these materials are heated [225] and the hazards involved in handling red phosphorus have led to the development of halogen- and elemental-phosphorus-free flame retardants based on melamine cyanurates that function by generating molecular nitrogen upon decomposition, which smothers the flame [226], [227]. More recently, flame retardants comprising a mixture of phosphinates and melamine cyanurates or melamine phosphates have been introduced [228].

Flame-retardant polyamides have many automotive, electrical, and electronics applications. One survey discusses control of tracking (formation of a conducting path on the polymer surface) [229]. Another review addresses properties of glass-reinforced thermoplastics including PA 6, PA 66, and PA 610 [230]. Colorants can increase flammability [231]. Safety is increasingly stressed and is generating even greater concern for smoke suppression and the toxicity of gases formed during combustion as well as the inhibition of ignition and flame support [225].

6.3.4. *Conductive Polyamides*

The burgeoning market for electronics has led to a great demand for electrically conductive polymers. Electronic devices generate radio frequency radiation during operation, and to prevent the consequent electromagnetic interference (EMI) with other devices, it is necessary to shield the source with an electrically conductive material. Since polyamides are not intrinsically conductive, EMI shielding of nylon parts can be accomplished in either a two-step process that involves coating the plastic with a conductive material, or, preferably, filling it with a conductive additive, such as carbon fibers, metal-coated carbon or glass fibers, metal fibers, carbon black, or graphitic carbon fibrils [232], [233].

It should be noted that neat and glass-reinforced nylons have also been successfully used for some time in electrical power engineering and electronics [234]. A variety of plastics containing metal fillers or carbon to make them electrically conductive, including PA 66, were exposed to an aqueous detergent solution at 25 and 80 °C and to isopropyl alcohol; the effect on EMI shielding was assessed [235]. The compositions with carbon generally outperformed those with metal fillers. The only PA 66 evaluated contained carbon fibers, and its retention of shielding was equivalent to that of the other materials tested.

Unadulterated polyamides are *thermal insulators*, but when combined with heat-conductive additives such as graphite fibers or ceramics like boron nitride and aluminum nitride, they can be used in heat-removal applications that include heat sinks for electronics and electrical applications [236].

6.3.5. *Other Formulations*

The amount of polyamide used and the nature of its dispersion in a blend with other polymers may be such that it is properly defined as the modifier rather than the base resin. One commercial example is a blend of nylon and poly(2,6-dimethyl-*p*-phenylene oxide). Allusion has been made to a blend with poly(phenylene sulfide) as the major ingredient [237]. Another composition presumably involves mostly ABS and some nylon [238]. A developmental material is a glass-reinforced blend of polycarbonate and nylon [239]. The literature on blends is voluminous. Brief reviews of all commercial blends including some commentary on their processing are given in [237-239]. A recent text focuses specifically on commercial blends and alloys [240]. It may reflect success in finding a compatibilizing agent for essentially incompatible polymers.

A different kind of product in which nylon is the principal component arises from reaction during molding of pellets that differ in chemical constitution; at least one component is caused to form a cross-linked structure. In one commercial case a pseudo- or semi-interpenetrating network (SIPN) results which physically binds a silicone modifier to a nylon matrix [241].

With the appropriate additives, polyamides can be used in a variety of specialized applications. For example, polyamides can be combined with magnetic materials such as neodymium-iron-boron alloy powders, permitting the injection molding of magnetic parts [242].

High-density polyamide formulations can be obtained by compounding with metal fillers and powders such as aluminum, zinc, steel, tungsten, or lead. The densities of the materials can be fine-tuned by using metals of different densities and varying their loadings. Addition levels of up to 95 wt % have been achieved. However, the polymer can still comprise 40–70 % of the volume, which permits these compositions to be processed using standard equipment. Wear and abrasion on extruder barrels, screws, and molds is an issue and hardened steel tooling is recommended. These polyamide metal

materials can serve as substitutes for metal in both practical (such as for X-ray and radiation shielding applications, fishing-line sinkers, and bullets) and aesthetic applications. In the former, the substitution of moldable plastics for metal parts permits a greater degree of design freedom. In the latter, the added heft and metallic feel given to the plastics creates a perception of greater value [243-245].

Rigid parts made from polyamides can be given soft coatings by overmolding them with thermoplastic elastomers. Suitable elastomers include polypropylene-EPDM thermoplastic vulcanizates that contain small amounts of polyamide block copolymer to serve as a compatibilizer. Such “soft-touch” materials have a variety of applications in consumer goods [246], [247]. Alternatively, block copolymers of polyethers and polyamides have elastomeric properties and their hardness can be tuned over a wide range. These materials can be overmolded onto other materials for a variety of consumer, industrial, automotive, and adhesive applications [248] (⟶Thermoplastic Elastomers).

The amount of polyamide used and the nature of its dispersion in a blend with other polymers may be such that it is properly defined as the modifier rather than the base resin. One commercial example is a blend of nylon and poly (2, 6-dimethyl-p-phenylene oxide). Allusion has been made to a blend with poly(phenylene sulfide) as the major ingredient [194]. Another composition presumably involves mostly ABS and some nylon [195]. A developmental material is a glass-reinforced blend of polycarbonate and nylon [196]. The literature on blends is voluminous. Brief reviews of commercial blends including some commentary on their processing are given in [194-196]. A recent text focuses specifically on commercial blends and alloys [197]. Blends in which there is some level of bonding between matrix and modifier, whether due to likeness of solubility parameters, hydrogen bonding, or some other factor are sometimes termed alloys.

[Top of Page]

7. Processing

Nylons are processed into useful articles by a variety of techniques—injection molding, extrusion, blow molding, monomer casting, solution coating, fluidized-bed or electrostatic coating, or forming [19]. The major fraction of the annual polyamide volume is processed by injection molding, extrusion, and blow molding. Each of these melt processes requires different melt viscosities for optimum processing. Whereas injection molding requires the lowest melt viscosity, for extrusion and blow molding a high melt strength is needed, which by necessity requires a high melt viscosity. Molecular mass can be altered to meet the viscosity required for the desired process. In addition, modifying molecular architecture is sometimes used to alter the rheological properties (see Section Control of Rheological Properties.).

Equation (12) governs the dynamics of the amidation/hydrolysis equilibrium in polyamides. The polyamide molecular mass will either increase or decrease, and consequently the melt viscosity, as well, depending on whether the moisture content is higher or lower, respectively, than the equilibrium moisture content. Thus, moisture control in polyamide melt processing is extremely important and because of the ubiquitous nature of moisture it is often the most difficult to control. Most problems in nylon processing could be attributed to poor control of moisture. These problems can manifest themselves in mechanical properties, appearance, and processibility.

Good flow and fast set-up make nylons relatively easy to process. Standard three-stage screws with or without mixing heads, corotating twin screws, and barrier screws with or without venting are all used. Most reciprocating screws in injection molding are of standard type. Moisture content should be somewhat lower for extrusion than for injection molding because the absence of high die pressure facilitates volatilization. Control of moisture to avoid hydrolysis or polymerization is always a concern. Processors use dehumidifiers to control the moisture present in molding materials especially when using regrind or while operating under hot, humid conditions. Failure to compensate for changes in molecular mass during measurement of melt viscosity because of failure to control moisture content adequately, e.g., by over drying has resulted in questionable estimates of the activation energy of viscous flow. Thermal degradation can also be a problem if the melt is held too long at too high a temperature. Thus, one study preferred to use a capillary mounted on an injection molding machine rather than an Instron capillary rheometer in part because of shorter hold-up times [249]. Values of 42–63 kJ/mol for the activation energy of viscous flow appear reasonable rather than those of 71–92 kJ/mol as have sometimes been reported [19], [250]. Master curves that are based on only the T_g and melt flow index (MFI) per ASTM D 1238 have been proposed for a number of polymers including nylons [251]. These curves plot the product of viscosity and MFI against shear rate divided by MFI. The sample curves in Figure 15, mostly at 280 °C, were taken from [252-255]. As shown in the figure, the apparent melt viscosity of the linear, aliphatic nylons starts to decrease rapidly at a shear stress of ca. 50 MPa.

Figure 15. Dependence of apparent melt viscosity on apparent shear rate for various nylons at 280 °C (adapted from [19])

a) Nylon 610 [254]; b) Nylon copolymer [254]; c) Nylon 66, M_n ca. 18 000 [253], [254]; d) Nylon 6, M_n ca. 20 000 [253]; e) Nylon 6, M_n 19 100 at 203 °C [252]; f) TMDT at 250 °C [255]; g) Nylon 66, M_n ca. 34 000 [253], [254]; h) Line of constant shear stress of 50 MPa

Filled and reinforced nylons have higher melt viscosities than their neat analogues, but the differences become smaller as the level of shear increases [256], [257]. Processing variables affect the ultimate fiber size in the blend and can accordingly affect the properties of the molded product [258], [259]. Compounding studies indicated that the major fiber degradation occurs in the melting region [260]. A subsequent study came to the same conclusion and showed fiber fracture to be independent of fiber concentration and dispersion and to arise from fiber interaction with shear in the matrix [261].

Toughened nylons also tend to have higher melt viscosities than their neat counterparts. There is again diminution of the difference as shear increases. The lower modulus implies longer molding cycles, but in at least one case the toughener induced nucleation which made for fast molding [216].

[Top of Page]

8. Uses

Nylons are used in many and diverse ways. They are found in appliances, business equipment, consumer products, electrical/electronic devices, furniture, hardware, machinery, packaging, and transportation. This diversity makes classification and analysis difficult as shown in Table 8 which compares the pattern of consumption in the United States [200] with that in Western Europe [262].

Table 8. Pattern of nylon consumption in the North America and Western Europe in 2001 [262]

Class	Percentage use in	
	North America	Western Europe
Appliances and power tools	1.4	4.6
Consumer products	7.8	6.5
Electrical and electronic applications	7.6	19.3
Extrusion markets	13.1	24.1
Industrial equipment	9.0	6.5
Miscellaneous injection molding		3.4
Other	16.5	3.4
Transportation	44.5	32.2
Total percent	100	100
Total production, t/a	507 000	679 600

Transportation is the largest market for nylons. The good performance of nylon at high temperatures and pressures, as well as its chemical resistance and compatibility with many automotive fluids, along with the design flexibility available with plastics, paved the way for the adoption of polyamides in many under-the-hood applications. The introduction of high-performance mineral reinforced and glass reinforced versions of nylon greatly increased the ability to tailor properties for individual engine components. When government regulations required automobile manufactures to install pollution-control devices, designers turned to these proven materials for critical air and fuel system control components because of the polymer's performance and the relative ease of part manufacture. Utilizing nylon in the engine compartment reduces weight, which can improve fuel efficiency without sacrificing engine performance. Key developments were pioneered in Europe where smaller cars, higher gasoline costs, and emission control mandates drove innovation. Soon, commercial applications of nylons in air intake manifolds, brake fluid reservoirs, power steering reservoirs, and radiator end tanks were introduced. These developments gained footholds in Europe and spread to U.S. automobiles. Unreinforced resins are used in electrical connectors, wire jackets, windshield wiper and speedometer gears, and emission canisters. The softer nylons are used in fuel lines, air brake hoses, and spline shaft coatings. Glass reinforced nylons are used in engine fans, radiator headers and grilles, brake and power steering fluid reservoirs, valve covers, air intake manifolds, wheel caps, air brake contacts and head-rest shells. Applications for nylons combining tougheners and reinforcement include brackets, steering wheels, and accelerator and clutch pedals. Mineral-filled resins are used in wheel caps, radiator grilles, and mirror housings. Nylons containing both glass fibers and minerals are used in exterior parts such as fender extensions. Toughened nylons are found in stone shields and trim clips.

Electrical and electronic applications comprise a major market for nylons, albeit more so in Western Europe than in the United States. Flame-retardant materials are particularly important in this area. Uses include color-coded components, plugs, connectors, coil forms, wiring devices, terminal blocks, antenna mounting devices, and harness ties. A review of nylon in electrical power engineering and electronics has already been cited [234]. Wire and cable jacketing is used mostly over primary insulation because of the solvent, wear, and abrasion resistance of nylons. Relays, fittings, and contact makers constitute a partial list of applications in telecommunications.

Industrial applications are attracted to the excellent fatigue resistance and repeated impact strength of nylons. Examples are hammer handles and moving machine parts. The mechanical strength accounts for use in gears, bearings, antifriction parts, snap fits, and detents. Food- and textile-processing equipment, pumps, valves, agricultural and printing devices, and business and vending machines comprise a partial list of other industrial uses.

Consumer products exploit the toughness of nylons in ski boots, ice and roller skate supports, racquet equipment, and bicycle wheels. Kitchen utensils, toys, photographic equipment, brush bristles, fishing line, sewing thread, and lawn and garden equipment show that the breadth of utility of nylon also includes consumer products.

Appliances and power tools make use of the impact strength of nylons. Glass-reinforced resins, which combine stiffness at high temperatures with toughness and grease resistance, are used in handles, housings, and parts in contact with hot metal. Sewing machines, laundry equipment and dishwashers are examples of other appliances that have utilized nylons.

Film applications have grown in importance because of the use of nylons in coextruded, composite films for food

packaging. Polyamides are also used in cook-in bags and pouches. Another development involves dispersion of nylon platelets in a polyolefin matrix to combine both hydrocarbon and moisture barrier properties in blow molded containers [263], [264].

Heat Exchangers. A recent new application utilizing nylon resin in is heat exchangers for heating, ventilation, and air-conditioning (HVAC) applications (developed by Du Pont, trade name Caltrel®). Air-to-liquid exchangers provide heating, cooling and dehumidification for passenger cars and military vehicles. Air-to-air and liquid-to-liquid exchangers have been developed for industrial end uses such as in office buildings and restaurants.

Nylon provides excellent resistance to attack by chemicals, solvents, encrustation buildup, galvanic corrosion, and microbiological agents. These exchangers can endure in many environments, including areas near saltwater or exposed to aggressive vapors and fluids. Nylon has lower maintenance costs than metal because components have smooth internal surfaces that resist buildup of mineral deposits and debris, which often constrict fluid flow and decrease heat transfer performance of comparable metal heat exchangers. Any buildup is quickly and easily removed by flushing at moderate pressure.

Two significant advantages of nylon heat exchangers are their light weight and that they permit great design flexibility, allowing them to be adapted to many environments. Having lower weight is a continuing goal of the automotive industry, and the utilization of nylon makes the exchangers lighter and thus easier to install. The use of nylon also allows the units to be easily contoured to fit the available space, which is especially valuable in tight areas such as under the hood of an automobile [265].

Others Applications. The soft polymer-modified, anionically polymerized caprolactam has been used via RIM to make machine housings, grain buckets, and fuel tanks [266]. Blow molding compositions [267], PA 46 and MXD 6 continue to extend the utility in the market [268-270]. Products with improved processing characteristics, high- and low-temperature performance, and new property profiles obtained via the use of new modifications and combinations thereof are continually appearing [271], [272]. A PA 6 with reduced moisture sensitivity has been demonstrated [269], as has the use of block copolymers as thermoplastic elastomers [248].

The adaptability of nylon to be changed to even obtain diametrically opposite results is shown in Figure 16, which gives some examples of the applications involved. Nylons with qualified approval in the United States in 2002 for processing, handling, and/or packaging food are PA 66, 610, 66/610, 6/66, 11, 6, 6T/66, 612, 12, MXD6 and impact-modified MXD6, 12/AI (A = bis(4-amino-3-methylcyclohexyl)methane [6864-37-5]), 6I/6T, 6/69, 46, and TMDT [273].

Figure 16. Nylon readily tailored to market needs

[Top of Page]

9. Ecological Aspects and Toxicology

9.1. Recycling

Polyamides are quite stable, and are used primarily in durable applications that are not major contributors to the waste stream. Scrap and trim are generally reused during processing, further minimizing waste. Some consumer applications such as bristles, strapping, and composite film for packaging do involve routine disposal, but the total is well below 0.05 wt % of all collected refuse. As a result, commercial nylon recycling processes are not as well developed as they are for other thermoplastics. However, it is far more energy efficient to recycle nylon than to burn it [274], and European directives in 2001 that phase in a requirement that almost all plastics used in automobiles be recycled over the subsequent two decades will continue to spur development in the recycling of mixed thermoplastics. Several commercial initiatives to recycle readily-available PA 6 and PA 66 carpet fibers are also underway in the United States and Europe, but have met with mixed success at the outset due to low demand and the difficulties of efficiently and economically collecting raw materials [275-278].

Difficulties involved in recycling post-consumer polyamides include the fact that they are often used compounded with a wide variety of additives (see Section Modification by Additives), that need to be removed and the fact that the properties of polyamides generally suffer greatly upon multiple reheatings, as the polymers tend to degrade and lose molecular mass. Most of the current commercial recycling processes involve the depolymerization of the polymer chains and isolation of the monomers, which are then used as feedstocks to make near-virgin polyamides. PA 6 can be depolymerized to caprolactam by heating the polymer in the presence of superheated steam and an acid catalyst such as phosphoric acid and collecting the monomer by distillation [279], [280]. PA 66 or PA 6 can be depolymerized by ammonolysis, which involves heating the polymer with ammonia at elevated pressures in the presence of a Lewis acid catalyst to yield hexamethylenediamine (HMD) or caprolactam and a series of nitriles and amides, some of which can be hydrogenated to yield HMD or caprolactam precursors [281], [282]. Other methods exist that convert PA 66 or PA 6 to adipic acid by treating the polymers with an aliphatic acid at elevated temperatures and oxidizing the resulting alkylamides and bisalkyamides [283].

Depolymerization followed by repolymerization is an expensive process, however, and mechanical recycling of polyamides, which involves grinding or crushing the resin, followed by pelletizing, is also used, although the resulting resins are of lower quality and have limited uses. A solution-based polyamide recovery process has been developed in which the polymer is dissolved in an anhydrous polyol or aliphatic carboxylic acid at elevated temperatures, insoluble fillers are removed by filtration, and more solvent at a sufficiently low temperature to cause the polyamide to precipitate is added quickly [284]. As a result of the rapid quenching, this process leads to relatively little degradation of the polymer, which can be then be reused. A disadvantage of this process, however, is that the resulting solutions are quite viscous, which makes filtration through fine filters, and hence the removal of submicron particles, such as titanium dioxide (which is often used in polyamide fiber applications) difficult. To address this problem, a process was developed to partially depolymerize a polyamide dissolved in methanol or ethanol to achieve a viscosity suitable for filtration, separate the insoluble material, and then repolymerize the recovered low molecular polymer by solid-phase or melt polymerization [285].

9.2. Polyamide Monomers

Most polyamide monomers come from petroleum-based feedstocks, although two commercially important monomers, sebacic acid (decanedioic acid) and 11-aminoundecanoic acid, are derived from castor beans. The processes for preparing many common monomers often use ingredients that can generate byproducts and thus must be handled carefully. For example, adipic acid is generally produced by oxidizing a mixture of cyclohexanone and cyclohexanol with nitric acid, generating nitrous oxide, which is believed to be a greenhouse gas, as a byproduct. These byproducts are contained under rigorous manufacturing controls and not released into the environment. A variety of research projects have addressed these issues. A process has been developed that oxidizes benzene to phenol with nitrous oxide. The phenol is converted to cyclohexanone, which is oxidized to adipic acid with nitric oxide, and the resulting nitrous oxide byproduct is recycled back into the process [286], [287]. Recently a method has been reported to directly oxidize hexane to adipic acid in the presence of air using molecular sieves containing cobalt(III) ions [288]. A method has been developed to oxidize *p*-xylene to terephthalic acid using a heterogeneous catalyst in supercritical water [291].

9.3. Other Aspects

Polyamides degrade slowly in sunlight with the evolution of organic acids, aldehydes, and oxides of carbon. These are assimilated with other natural decomposition products. Resistance to attack by bacteria and fungi makes for very slow decomposition when buried in the soil. Nylons are normally inert, nonleaching, and well compacted in sanitary landfills so they pose no danger to subsurface water. Normal incineration in air at 800 °C yields the same gaseous products as do naturally occurring, proteinaceous materials such as wool, silk, hair, and leather, i.e., mainly carbon dioxide and carbon monoxide with small amounts of ammonia and hydrogen cyanide. Silk generates more of these products than does PA 66 under the indicated conditions of incineration.

Most polyamides are biologically inert and offer no toxicological problems except, possibly, in the instance of additives or some low molecular mass fragments. Caprolactam monomer has been reported to be a convulsant poison in sufficient doses although aminocaproic acid is not [290]. The same comment is applicable to the dermatological situation—no problem with the polymer but caution with respect to additives and caprolactam. Polyamides have been widely used as a suture material and many are approved for food uses. The use of wood fiber as a light-weight reinforcing agent in polyamides that comes from a renewable resource and leaves no ash upon incineration has also been investigated [292]. Polyamides can contribute to decreased emissions and fuel consumption when they replace heavier metals in automotive applications and can replace toxic metals in certain applications (see Section Other Formulations).

[Top of Page]

10. Economic Aspects

Modern Plastics publishes an annual review of new developments and market trends and usage data for most major thermoplastics in its February issue (the January issue prior to 2000) and many October issues of *Kunststoffe* publish reviews of new developments and market changes. *Plastics Technology* lists prices monthly. These have all contributed to the information provided in this article.

Consumption of polyamides in Western Europe has grown from 200 000 t/a in 1980 to 679 000 t/a in 2001, which corresponds to an average annual compounded growth rate of about 6 %. In the United States, consumption of polyamides has grown from 100 000 t/a in 1976 to 507 000 t/a in 2001, corresponding to an average annual compounded growth rate of 6–7 %. In Japan, consumption has grown from 186 t/a in 1994 to 267 t/a in 2000, before dropping back to 246 t in 2001, corresponding to an average annual compounded growth rate of 4–5 % between 1994 and 2001. Year to year changes are not uniform, and significant annual dips have occurred as a result of economic forces.

Major market segments worldwide for injection-molded polyamides are appliances/power tools, consumer products, electrical and electronics, and transportation. In the United States the average annual compounded growth for the first four was 4–5 % between 1988 and 2001, although the appliance segment experienced a sharp drop to 1988 levels between 1999 and 2001. The transportation/automotive segment is easily the largest and fastest growing, with an annual rate of 9–10 % between 1988 and 2001 and comprised about 44 % of the polyamide plastics market in 2001. A high of 254 t was consumed in 2000, but consumption dipped to 226 t in 2001. Between 1988 and 2001 the ratio of consumption for molding applications to extrusion applications ranged from about between two and three to one. Extrusion applications dipped sharply in 2000 and 2001 back to 1988 levels, however, and between five and six times more polyamide was consumed for molding applications than extrusion applications in those years.

In Europe, the largest and fastest growing area is also the transportation/automotive segment, which experienced an average annual compounded growth rate of 9–10 % between 1994 and 2001 and comprised about 32 % of the polyamide market in 2001. The other molding application segments grew at about 4–7 % during the same time period. Extrusion applications continued to grow at a rate of about 7–8 % during this time period. The ratio of consumption for molding applications to extrusion applications was fairly steady at about three to one during this time period.

Producers of polyamides are listed with their products and trade names in Table 9.

Table 9. Major producers of polyamides

Company	PA 6	PA 66	Other	Trade names
Asahi		x		Leona
Atofina	x	x	11, 12	Rilsan, Orgamid, Cristamid, Platamid
BASF	x	x	610	Ultramid
Bayer	x	x		Durethan
Degussa			12, amorphous	Vestamid, Trogamid
DSM	x	x	46, 610	Akulon, Stanyl
DuPont	x	x	612, phthalamides, amorphous	Zytel, Minlon
EMS-Grivory	x		12, amorphous	Grilon, Grilamid, Grivory
Enichem (Polimeri Europa)	x			Nivionplast
Honeywell	x	x		Capron
Mitsubishi Engineering-Plastics	x	x		Novamid
Mitsubishi Gas			MXD6	Reny
Mitsubishi Petrochemicals			phthalamides	Arlen
Rhône-Poulenc	x	x	610	Technyl
Snia Tecnopolimeri	x	x		Sniamid, Nailonplast
Solutia		x		Vydyne
Solvay			MXD6, phthalamides	Ixef, Amodel
Ticona	x	x		Celanese
Toray	x	x	610, 12	Amilan
Ube	x	x	12	Ube
Unitika	x			Unitika

1. Introduction

The economically most important polycarbonate is 2,2-bis(4-hydroxyphenyl)propane polycarbonate (**1**), also termed bisphenol A polycarbonate [*24936-68-3*] (BPA-PC).

1

It was discovered by SCHNELL, BOTTENBRUCH, and KRIMM in 1953 at Farbenfabriken Bayer (now called Bayer), and independently by FOX at General Electric shortly afterwards [1], [2]. The polymer was first produced industrially and introduced to the market in Europe in 1958 by Farbenfabriken Bayer and in the United States in 1960 by Mobay Chemical Corporation (now called Miles Inc.) and General Electric.

The great commercial success of BPA-PC is due to its unique combination of properties: extreme toughness, outstanding transparency, excellent compatibility with several polymers, and high heat distortion resistance.

In addition to bisphenol A (BPA), many other bisphenols have been converted to polycarbonates [1–7]. However, very few of them have been used as monomers in industrial polycarbonate production (Section 2.2).

Examples include 1,1-bis(4-hydroxyphenyl)cyclohexane [*843-55-0*] (bisphenol C, BPC) (**2**), 2,2-bis(3,5-dibromo-4-hydroxyphenyl)propane [*79-94-7*] (tetrabromobisphenol A, TBBPA) (**3**), and 2,2-bis(3,5-dimethyl-4-hydroxyphenyl)propane [*5613-46-7*] (tetramethylbisphenol A, TMBPA) (**4**):

2

3

4

BPC is used as a comonomer for bisphenol A in special polycarbonates for cast film production to reduce the crystallization tendency of the polycarbonate during the cast-

10.1002/14356007.a21_207

ing procedure. TBBPA is cocondensed with bisphenol A to increase the flame resistance of the polycarbonate. TMBPA polycarbonate [4] is highly heat resistant and has a low melt viscosity. It can be mixed with BPA-PC, polystyrene, styrene – acrylonitrile copolymers with a low acrylonitrile content (e.g., 10 wt %), or poly(vinyl chloride) to give a single phase [4], [6]. It was commercially available for several years from 1978 onwards. It is now used in small quantities and blended with BPA-PC, poly(butylene terephthalate), and impact modifiers to elevate the heat distortion resistance of polycarbonates [6]. More recently, 1,1-bis(4-hydroxyphenyl)-3,3,5-trimethylcyclohexane [*129188-99-4*] (BPTMC) (**5**) has become important for the production of highly heat resistant polycarbonates [8] which have been on the market since 1990.

5

BPA-PC may be modified not only by cocondensation of bisphenol A with other bisphenol monomers, but also by cocondensation with blocks of other polymers. Aromatic polyester blocks [9], [10], aliphatic polyether blocks [11], and polysiloxane blocks [6], [12] have become industrially important in this respect (Section 2.2).

2. Properties

2.1. Bisphenol A Polycarbonate

BPA-PCs are soluble in chlorinated hydrocarbons (e.g., chloroform, dichloromethane, and dichloroethane) and nonhalogenated solvents (e.g., pyridine and *m*-cresol). They are insoluble in water, alcohols, and (cyclo)aliphatic hydrocarbons. BPA-PCs are generally amorphous and thus transparent when processed by injection molding or melt extrusion, or when cast from solution into films. They can, however, be crystallized by special treatment, for example, by heating at temperatures between the softening point and the crystalline melting point (ca. 260 °C), by treatment with solvents (e.g., acetone and toluene), or by stretching fibers or films [2].

Table 1. Properties of bisphenol A polycarbonate (Makrolon 2800, Bayer)

Property	Test standard	Value
Ultimate tensile strength, N/mm^2	ISO/R 527	72
Elongation at break, %	ISO/R 527	120

Surface resistivity, Ω	IEC 93	10^{15}
Volume resistivity, Ω · cm	IEC 93	10^{16}
Dielectric constant (dry) (50 Hz/1 kHz)	IEC 250	3.0/3.0
Dielectric loss factor (dry) tan $\delta \times 10^4$ (50 Hz/1 kHz)	IEC 250	9/10

Some properties of a standard BPA-PC are given in Table 1. Industrial BPA-PCs for injection molding and extrusion have weight-average molecular masses ($\bar{M}_W$) of 20 000 – 35 000. BPA-PC melts with molecular masses exceeding 60 000 cannot be processed due to their extremely high melt viscosity. These high molecular mass polycarbonates can, however, be cast from solution into films with desirable properties (Makrofol, Bayer). See also, →Films, Chap. 6.9.

$x = 5-200$ **6**

The toughness and impact strength of BPA-PC are considerably higher than those of other amorphous, single-phase thermoplastics [e.g., polystyrene, poly(methyl methacrylate), and polysulfone]. The tough fracture of BPA-PC changes to a brittle fracture below − 10 °C or when the molding thickness exceeds ca. 6.5 mm [13].

The high transparency of BPA-PC and its high heat resistance (T_g ca. 150 °C which is 50 °C above that of polystyrene) are very important for its uses and applications. The long-term stability of BPA-PC against heat aging in air is ca. 130 °C depending on the test method; the compound starts to decompose at 400 °C. BPA-PC has a low flammability (oxygen index 26). Its flame resistance can be improved considerably by adding small amounts of flame retardants (see Section 2.3).

2.2. Modified Bisphenol A Polycarbonate

Injection molding is generally used to process BPA-PCs with weight-average molecular masses $\bar{M}_W$ of 20 000 – 35 000. At lower molecular masses the mechanical properties (e.g., toughness and elongation at break) deteriorate sharply; within the above range they increase with increasing molecular mass. As the mechanical properties continue to increase above $\bar{M}_W$ 35 000, the melt viscosity becomes very high and prevents injection molding. The mechanical properties of low molecular mass polycarbonates with a low melt viscosity can be improved by introducing branched alkylphenols instead of simple phenols as chain terminators [8], [14].

The introduction of branching points in the polymer chain by incorporating small amounts of polyfunctional compounds (e.g., trifunctional phenols) produces BPA-PCs whose melts have a high structural viscosity [6], [8], [15–18]. These polymers are particularly suitable for melt extrusion because they have a low viscosity under the shearing action in the extruder, and after leaving the extruder nozzle they are highly viscous and thus sufficiently stable. Complicated extrudates, such as twin-wall sheets, can be produced with high accuracy. The structural viscosity of melts of these polycarbonates is also important for the production of large hollow articles by extrusion blow molding (e.g., 20 L water bottles).

BPA-PC exhibits tough fracture and outstanding notched impact strength (ISO 180/4 A) above − 10 °C. Below − 10 °C however, the tough fracture changes to a brittle fracture and the notched impact strength is considerably reduced. The notched impact strength at low temperatures can be improved by incorporation of polysiloxane blocks [6], [12]; this shifts the tough – brittle transition to below − 40 °C. A siloxane content of 2 – 10 wt % produces a satisfactory effect.

Polydimethylsiloxane blocks are coupled to the polycarbonate via the bisphenol A residues (**6**) (see above).

Incorportation of aliphatic polyether blocks into BPA-PC produces hydrophilic polycarbonate – polyether block copolymers, which are of interest as hemodialysis membranes [11].

Partial replacement of the carbonate groups in BPA-PC by terephthalate or isophthalate groups leads to aromatic polyester carbonates with a higher heat distortion resistance and a higher stability against heat aging in air [9], [10].

Depending on the proportion of polyester and the terephthalate – isophthalate ratio, the glass transition temperature is between ca. 150 and 210 °C (i.e., the glass transition temperatures of BPA-PC and bisphenol A – terephthalic acid polyester, respectively). Aromatic polyester carbonates are, like BPA-PC, extremely tough and transparent. However, they have a significantly higher melt viscosity and a pale-yellow color.

The flame-resistance of BPA-PC can be improved by cocondensing small amounts of tetrabromobisphenol A (**3**) with bisphenol A. Partial or total replacement of bisphenol A in BPA-PC by tetramethylbisphenol A (**4**) increases the glass transition temperature from 150 to 203 °C [4] without reducing the flowability in injection molding.

The glass transition temperature of BPA-PC can be increased even further by partial or total replacement of bisphenol A by 1,1-bis(4-hydroxyphenyl)-3,3,5-trimethylcyclohexane [8]; glass transition temperatures of ca. 150 to 240 °C can be achieved in this way. These polycarbonates are transparent, tough, and colorless, even at high glass transition temperatures [8]. Their melt viscosities are favorable compared

with those of aromatic polyester carbonates, polysulfones, polyethersulfones, and polyetherimides having the same glass transition temperature.

BPA-PC is used in polymer blends (→ Polymer Blends, Chap. 4.6.). The most important blends are those with acrylonitrile – butadiene – styrene (ABS) graft polymers [6], [19], [20] and those with poly(butylene terephthalate) or poly(ethylene terephthalate), and impact resistance modifiers (e.g., ABS) [6], [19], [21]. Compared to ABS, BPA-PC – ABS blends have improved heat resistance. They also exhibit good processibility, light stability, surface quality, and high toughness, even at low temperature (tough fracture in the notched impact strength test). Blends of BPA-PC with poly(alkylene terephthalates) and impact strength modifiers have a high heat distortion resistance, and high toughness even at low temperature. Their resistance to gasoline and other solvents is better than that of BPA-PC.

2.3. Bisphenol A Polycarbonate with Additives

Most of the additives discussed in this section are described in detail elsewhere (→Plastics, Additives).

Mold-Release Agents. The addition of small amounts (< 1 wt %) of mold-release agents (e.g., fatty acid esters of higher alcohols, such as pentaerythritol or glycerol) to the polycarbonate improves the mold release of complicated parts [6]. See also → Release Agents.

Flame Retardants. The flame resistance of BPA-PC can be increased by incorporating tetrabromobisphenol (see Section 2.2) or by using additives or additive combinations [6]. For example, flame resistance is significantly improved by the addition of small amounts (< 1 wt %) of special salts, such as potassium perfluoro-*n*-butane-1-sulfonate, sodium 2,4,5-trichlorobenzenesulfonate, and potassium diphenylsulfone-3-sulfonate [22–25]. The tendency to form flaming drips after ignition can be reduced by using branched polycarbonates (see Section 2.2) or by adding small amounts (< 1 wt %) of polytetrafluoroethylene [26].

Light Stabilizers. Ultraviolet light, especially in combination with atmospheric oxygen and moisture, causes decomposition of BPA-PC. Decomposition starts with a photo-Fries rearrangement, which leads to the formation of salicylates, followed by benzophenones [6], [7]. These structures absorb visible light in the short-wavelength region and are thus responsible for the yellowing of polycarbonates. Stabilization against degradation by UV light (i.e., against yellowing) is important for exterior uses and applications and can be achieved by adding small amounts (< 1 wt %) of benzotriazole derivatives [7].

Reinforcement. Glass fibers (< ca. 35 wt %) are generally added to the polycarbonate for reinforcement. They improve rigidity and stiffness, and lower the coefficient of thermal expansion [6], [7], [27].

Miscellaneous Additives. *Heat stabilizers* (e.g., organic phosphites) can be added to the polycarbonate to prevent thermal oxidation during processing at high temperature [6]. *Blowing agents* (e.g., 5-phenyltetrazole and phenyldihydroxo-oxadiazonone) can be added during thermoplastic processing into moldings to obtain low-weight foamed structures (→ Foamed Plastics, Chap. 4.15.) [6]. Transparent or opaque polycarbonates can be obtained in a wide range of colors by using *organic dyes* and *inorganic pigments.*

3. Production

3.1. Interfacial Polycondensation

Interfacial polycondensation is currently used for the industrial production of polycarbonates [2], [5], [6]. Bisphenol A is reacted with phosgene at 20 – 40 °C in a two-phase mixture consisting of an aqueous, alkaline phase and an immiscible organic phase. The overall reaction is as follows:

The bisphenol A is first dissolved in the aqueous phase as sodium bisphenolate and the phosgene is dissolved in the organic phase that generally consists of chlorinated hydrocarbons (e.g., dichloromethane). Reaction occurs at the phase interface to produce carbonate oligomers, which then enter the organic phase. A 10 – 20 mol % excess of phosgene (referred to the amount of bisphenol A) is generally used because a small proportion of the phosgene is hydrolyzed. The hydrolysis products (NaCl and Na_2CO_3) enter the aqueous phase. Relatively low pH values (9 – 11) are employed during phosgenation to minimize phosgene hydrolysis.

After the formation of carbonate oligomers, a catalyst is added. Tertiary aliphatic amines (e.g., triethylamine, tripropylamine, and tributylamine) are preferred as catalysts. They accelerate the polycondensation of oligomers to form high molecular mass products and catalyze the hydrolysis of excess terminal chlorocarbonate groups formed due to the excess of phosgene. This is important because the hydrolyzable chlorine contained in these groups would otherwise corrode the molds used during thermoplastic processing. During the polycondensation reaction the aqueous phase is kept at alkaline pH values (9 – 14).

Monofunctional phenols (e.g., 3 – 5 mol % phenol or 4-*tert*-butylphenol referred to bisphenol A) are added as chain terminators to the two-phase mixture before addition of the catalyst, to control the molecular mass. These compounds then form the terminal groups of the polycarbonate bound via carbonate groups.

Polycarbonate production can be carried out batchwise in stirred tanks or continuously in cascades of stirred tanks or in tubular reactors, in which the organic and aqueous phases are finely distributed by shear forces. After completion of polycondensation, the aqueous alkaline phase, which contains sodium chloride and sodium carbonate, is separated from the organic phase by centrifugation. The organic phase is then freed from residual traces of sodium bisphenolate by washing with dilute aqueous sodium hydroxide, followed by washing with dilute acid (e.g., hydrochloric or phosphoric acid) to neutralize the alkali. The organic phase is then washed free of electrolytes with demineralized water. All the wash stages are generally performed in separators.

Industrially, various processes are used to isolate the polycarbonate from solution. The most important are

1) Precipitation with nonsolvents for polycarbonate (e.g., heptane)
2) Precipitation by introduction of the solution into hot water and subsequent evaporation of the polycarbonate solvent
3) Evaporation of the solvent in an extruder

Polycarbonate is generally marketed in the form of granules, which are produced by melting the polymer in an extruder, extruding it as strands, cooling, and comminution. If the polycarbonate is isolated by evaporation of the solvent (chlorinated hydrocarbon) in an extruder, the granulate is obtained directly.

Stabilizing or modifying additives are generally incorporated into the polycarbonate during extrusion or in a subsequent compounding step.

3.2. Melt Transesterification

Diphenyl carbonate is transesterified in the melt with bisphenol A to form polycarbonate [2], [6]:

During this process phenol is split off and removed by distillation. Stirred tanks, helical reactors, or screw reactors (extruders) may be used. The reaction is usually catalyzed with very small amounts of alkali at 190 – 320 °C and reduced pressure (down to ca. 0.1 kPa). The temperature is initially low and the pressure is slightly reduced (e.g., 200 °C at 20 kPa). During the course of reaction the temperature is raised and the pressure reduced. Toward the end of the reaction the temperature must be high enough to maintain a sufficiently high melt flow, and the pressure must be as low as possible to remove all the eliminated phenol from the viscous melt. The polycarbonate is finally spun in the form of strands and granulated.

Although the melt transesterification process was the first industrial process for polycarbonate

production, it is no longer important. However, interest in it has revived due to the development of ecologically more favorable, phosgene-free production processes [8]. Reaction of carbon monoxide with alcohols in the presence of catalysts gives dialkyl carbonates that can, in turn, be reacted with phenol to form diphenyl carbonate [8]. The latter can then be reacted with bisphenol A, as described above, to produce polycarbonate by melt transesterification.

The melt transesterification process has also attracted renewed interest because of justifiable optimism that secondary reactions with deleterious effects on quality (e.g., discoloration) can be suppressed. This is achieved by using high-purity starting materials (diphenyl carbonate, bisphenol A), new catalyst systems, new high-viscosity reactors, and an alternative process route [8]. This route consists of the intermediate separation of an oligomeric carbonate produced by melt transesterification, which is then crystallized and subjected to solid-phase polycondensation.

4. Processing

Before thermoplastic processing, BPA-PC must be dried to a residual moisture content of < 0.02 wt % for the extrusion to < 0.01 wt %, usually at 120 °C. In modern, fast driers, drying times of 2 – 5 h are sufficient. It often makes sense to process the dried granulate in injection molding machines or extruders equipped with heated hoppers, so that it does not reabsorb moisture. Hoppers with circulating air heating (120 °C) are recommended. Moisture can also be removed during plasticization in the processing machine by means of a degassing unit. With very high temperatures or long residence times of the polymer melt the moldings should be checked for a decrease in molecular mass.

All modern injection molding machines are suitable for polycarbonate processing. Machines with three-section screws with a length – diameter ratio of 18 : 1 to 22 : 1 and a screw – channel depth ratio of 2 : 1 to 2.5 : 1 are recommended. The heating systems and regulating instruments must be designed for operation up to at least 350 °C: processing temperatures are generally 280 – 320 °C, the mold temperature should be 85 – 120 °C.

High-viscosity polycarbonates can be processed with extruders. Structurally viscous branched polycarbonates are particularly suitable for this (Section 2.2). Hollow articles, films, sheets, profiled sections, pipes, and strands are examples of extruded products.

Semifinished products can also be made from BPA-PC. Slow cooling in air or water from 80 °C without drawing the melt is required to obtain low-stress products. The temperature at the nozzle outlet is ca. 230 – 260 °C, depending on the melt strength. Films and sheets of BPA-PC can be subjected to thermoforming. BPA-PC can also be polished to a high gloss, coated, printed, embossed, or vacuum metallized, and bonded with solvents. Two-pack adhesives (e.g., epoxy, silicone, or polyurethane adhesives) are suitable for bonding BPA-PC parts to one another and to other materials. Parts made of BPA-PC may also be joined to each other by vibration, ultrasonic, friction, heated tool, and hot gas welding. The polymer can also be machined, sawed, and drilled.

High-quality films (2 – 200 μm thick) can be obtained by casting solutions of high molecular mass polycarbonates onto drums or bands (Section 2.1) and evaporating the solvent [7]. These films are particularly useful in the electrical sector (e.g., capacitors).

5. Uses

Electrical Sector. The electrical sector is the classical and major user of BPA-PC [8] because of the special combination of properties: outstanding electrical insulation, good flame retardance, high heat resistance, excellent toughness, dimensional stability, and transparency. The fact that these properties are largely independent of temperature and atmospheric humidity is also very important. Typical applications include housings for car telephones and distributor equipment, lamp sockets, multiple contact strips, relay parts, power plugs, safety switches, components for electronic calculators, fluorescent tube sockets, current meters, and winding supports. See also→Insulation, Electric.

Building and Construction. The building and construction industry has become the second most important user of polycarbonates [8].

The transparency, extreme toughness, and moderate price of polycarbonates make them suitable for window panes and roofing. Singly and multiply glazed panes are fabricated from solid polycarbonate sheets. Twin-wall and triple-wall sheets of polycarbonate combine optimum impact strength, good light transmission, light weight, and thermal insulation with minimal material consumption (low wall thickness) [28]. They are used as roofings for greenhouses, halls, and railway stations; as fences in ice hockey arenas; and as windows for telephone booths and gymnasiums.

Automobile Sector. In automobiles the high impact strength, heat resistance, transparency, and weather resistance of polycarbonates are especially important. Polycarbonate is used, for example, in headlight and taillight covers, reflectors, as well as fan and radiator grills. Polycarbonate – ABS blends have become very important in dashboards, where good heat resistance, high toughness, and tough fracture (splinter-free fracture) are required at low temperatures [6], [8], [29]. Blends of polycarbonate, poly(ethylene terephthalate) or poly(butylene terephthalate), and impact strength modifiers are also important [6], for example, in car bumpers, where low-temperature impact strength (down to $-40\,^{\circ}C$) and resistance to gasoline are necessary. The latter property is affected favorably by partially crystalline polyesters because they improve resistance to gasoline.

Optical Information Storage Systems. The use of BPA-PC for optical information storage systems is described in [6–8]. The best-known product in this area is the audio compact disc (CD), which is a read-only recording medium. For a complete description of optical recording, see→Information Storage Materials. Special polycarbonate grades fulfill the requirements of transparency, low birefringence, mechanical and dynamic stability, good heat distortion resistance and flow properties that are needed for CD production.

The information on a CD is stored digitally on the surface of the transparent polycarbonate in the form of small depressions (pits). The CD is produced by injection molding, and the pits are produced by using a mold with a stamper (→Information Storage Materials, Chap. 2.3.2.). The pits are scanned by a laser to retrieve the stored information (i.e., music). The same storage principle is employed in read-only memory (ROM) systems used to store data. In write-once read-many-times (WORM) memories the information can be "burnt" as a sequence of holes into a layer of rare-earth metal with a powerful laser beam. The sequence of holes can then be read as often as desired with weaker laser beams. This system is also termed direct read after write (DRAW).

The latest storage system, which has just come on the market, is the E-DRAW system (E = erasable). This system functions due to the effect of the different magnetizability of two very thin metal layers on top of one another. Laser beams of different strengths are used to write and read signals. These signals can also be deleted and rewritten as often as desired. As in the CD, ROM, and WORM (DRAW) systems, polycarbonate is used as a substrate for the E-DRAW data storage disc.

Miscellaneous Uses. Further important areas of use of polycarbonates include office equipment (casings, covers, keyboards), solution-cast films and extruded or coextruded films and sheets (cheque cards, cover sheets, capacitor sheets), foams (electrical distributor boxes, housings), medical applications (blood oxygenators, hemodialysis separating membranes, dialyzers, sterilizable equipment), packaging (baby bottles, water tanks, food containers), domestic applications (electric razors, sink units), and photographic or optical applications (camera cases, lenses, optical fibers).

6. Economic Aspects

Polycarbonate together with ABS (in 1989 about 2×10^6 t ABS were sold) and the thermoplastic polyamides (in 1989 about 8×10^5 t PA were sold, without fibers) belong to the top group of engineering thermoplastics [8]. Table 2 shows the volume of polycarbonate sold worldwide (including the PC proportion in blends) by manufacturers in the United States, Western Europe, and Japan (Triade). Production capacities for 1990 and those predicted for 1995 are also listed. Outside the Triade only Brazil had a low polycarbonate capacity (about 8000 t) in 1990. By

1995, however, important polycarbonate capacities (ca. 1×10^5 t) could exist in Korea, Brazil, and Taiwan [31].

Table 2. Worldwide polycarbonate sales volume (including the PC proportion in blends) and production capacities (10^3 t) [30]

Region	1990		1995 (predicted)	
	Sales	Capacity	Sales	Capacity
United States	260	353	356	427
Western Europe	186	266	250	363
Japan	110	153	162	238
Total	556	772	768	1028

The largest polycarbonate manufacturers are General Electric (1989: capacity 2.88×10^5 t, 45 % of world capacity of 6.36×10^5 t) and Bayer (1989: capacity 1.95×10^5 t, 31 % of world capacity) [31]. Trade names of General Electric products include Lexan (PC), Lexan PPC (aromatic polyester carbonate), Xenoy (PC – poly(butylene terephthalate) blends), and Cycoloy (PC – ABS blends). Trade names used by Bayer include Makrolon (PC), Makrofol (PC films), Makroblend (PC – polyester blends), Bayblend (PC – ABS blends), Apec (aromatic polyester carbonate), and Apec HT (BPTMC-based PC).

The amount of PC used in various sectors is subdivided as follows [8]:

Electrical/electronics, optical information storage media	49 %
Building and construction	24 %
Automobiles	8 %
Office equipment	6 %
Miscellaneous	13 %

7. Recycling

Polycarbonates exhibit a favorable behavior in both material recycling (reuse of polycarbonate after granulation of polycarbonate parts which are no longer required and are without chemical treatment) and chemical recycling. Chemical recycling is achieved by dissolving the polycarbonate in industrial solvents (e.g., chlorinated hydrocarbons), subsequent purification by filtration, and evaporation of the solvent [32]. In an alternative chemical recycling melted, the polycarbonate can be hydrolyzed, the bisphenol A is then recovered and reused in polycarbonate production [7], [33], [34].

For effective recycling operations, old polycarbonate parts that are no longer required (e.g., in automobiles or electrical equipment) must be collected separately. This constitutes a logistics problem that is not always easy to solve.

8. Toxicology and Environmental Aspects

Harmful effects of polycarbonates are not known [35]. Polycarbonates have not proved toxic when included in rat feed at a concentration of 6 % [36].

The toxicity of the gases produced by combustion of flame-resistant polycarbonates (according to DIN E 5346/37) is similar to or lower than that of wood, wool, or cotton [37]. For safety precautions, exhaust gas and wastewater control, and toxicology of phosgene (Section 3.1), see →Phosgene.

Polycarbonates can be used in accordance with the relevant laws for the production of toys, medical apparatus, and articles that are in contact with food provided that their composition complies with detailed regulations of the respective countries (e.g., Recommendation XI of the BGA, the German Materials and Articles Ordinance, the EEC Directive (90/128) on materials and articles for food contact, and the U.S. FDA regulation 21 CFR § 177.1580).

Polyester Resins, Unsaturated

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, Generals Survey; Plastics, Properties and Testing ; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated in Plastics, Properties and Testing . Fundamental aspects of polymerization reactions are treated in Polymerization Processes.

1. Introduction

Unsaturated polyester resins (abbreviated as UP resins according to DIN 7728, part 1) undergo cross-linkage to form thermosetting plastics (DIN 16 945). Most UP resins are medium- to low-viscosity, liquid solutions of unsaturated polyesters in copolymerizable monomers (usually styrene) as cross-linking agents.

Unsaturated polyesters are formed by polycondensation of unsaturated and saturated dicarboxylic acids with diols. UP resins are hardened (cured) or cross-linked by free-radical polymerization with initiators (e.g., peroxides) and accelerators at normal temperature (10–40 °C), or with peroxides alone above 80 °C. The unsaturated groups of the polyester chains react with the double bonds of the copolymerizable solvent monomer. Solid products are formed that are used as molding materials or in paints. They are also reinforced with fibers or filled, and used as putties or mortars.

Vinyl ester resins, which are also termed phenacrylate resins (DIN 16 946, part 2), are polyadducts of liquid epoxy resins and acrylic acid in styrene. Strictly speaking, they are not unsaturated polyester resins, but since they are processed, cured, and used similarly, they are also discussed.

2. Raw Materials

The properties of unsaturated polyesters depend on the nature and quantitative ratios of the raw materials (α-, β-unsaturated dicarboxylic acids, saturated dicarboxylic acids, and diols), as well as on the condensation conditions. Many different materials are quoted in the patent literature and in reference manuals [1–5]. However, only those described here are of practical importance. This limited number of raw materials has hardly changed since the early 1970s and permits wide variation as regards the processing and properties of UP resins.

A larger number of double bonds in the polyester chain increases the reactivity, the heat of reaction released during curing, and the thermal stability of the end product. The incorporation of long-chain dicarboxylic acids or diols increases the flexibility of the cured substance.

Unsaturated Dicarboxylic Acids. Maleic anhydride and fumaric acid are used almost exclusively as unsaturated acid components. They are described in detail elsewhere, see → Maleic and Fumaric Acids.

Maleic anhydride [*108-31-6*] is not as expensive as fumaric acid and contains one mole of water less than the free dicarboxylic acid, which is favorable for condensation. During condensation maleic acid largely rearranges into the isomeric form, fumaric acid. This rearrangement can also be promoted by catalysts.

Fumaric acid [*110-17-8*] is only used when the degree of rearrangement of maleic acid to fumaric acid is insufficient for the required properties of the UP resins. Use of fumaric acid instead of maleic anhydride in the condensation

10.1002/14356007.a21_217

improves the thermal stability and mechanical properties of the product. The disadvantages of fumaric acid compared with maleic anhydride are its higher cost and higher water content.

Saturated Dicarboxylic Acids. *Phthalic acid* [*88-99-3*] is used exclusively in the form of phthalic anhydride [*85-44-9*] (→ Phthalic Acid and Derivatives). On account of its favorable price and diverse potential uses, it is employed in all standard resins.

Isophthalic acid [*121-91-5*] (→ Terephthalic Acid and Dimethylterephthalates) has a better thermal stability, mechanical strength, and resistance to chemicals than phthalic acid.

Terephthalic acid [*100-21-0*] (→ Terephthalic Acid and Dimethylterephthalates) is used in resins where high impact strength, thermal stability, and weather resistance are required.

Tetrahydrophthalic anhydride [*935-79-5*] yields resins having a high impact strength but limited weather resistance. It is used primarily for resins employed in paints and automotive body fillers.

Adipic acid [*124-04-9*] (→ Adipic Acid) is used on account of its flexible carbon chain to produce soft resins and mixed resins that are employed to plasticize harder resins.

Hexachloroendomethylenetetrahydrophthalic (HET) acid [*115-28-6*] yields resins with low flammability and good chemical resistance.

Tetrabromophthalic acid [*13810-83-8*] also lowers flammability, but tends to produce strong discoloration in sunlight due to the release of bromine.

Diols. *Ethylene glycol* [*107-21-1*] (→ Ethylene Glycol) is inexpensive, but it sharply reduces the styrene compatibility of UP resins. It is generally used in combination with other diols such as diethylene glycol, dipropylene glycol, or butylene glycol.

1,2-Propanediol [*57-55-6*], propylene glycol, is by far the most widely used diol for standard resins (→ Propanediols). It has good styrene compatibility, only slight tackiness after curing in air, and good mechanical properties.

Diethylene glycol [*111-46-6*] and *dipropylene glycol* [*110-98-5*] result in plasticization of the resins and increased water absorption. They are used mainly in combination with 1,2-propanediol to adjust the mechanical properties or refractive index of the cured resin.

1,3-Butanediol [*107-88-0*], butylene glycol, (→ Butanediol) improves weather resistance, but is not used as often as the aforementioned diols on account of its high price and limited availability.

Neopentyl glycol [*126-30-7*], 2,2-dimethyl-1,3-propanediol (→ Alcohols, Polyhydric, Chap. 2.2.1.) increases the thermal stability, chemical resistance, and weather resistance of UP resins. Particularly when combined with isophthalic acid, it yields high-quality products for use in chemical plant construction.

Ethoxylated or propoxylated bisphenol A [*80-05-7*] is very often used for resins with a high thermal stability and extremely good resistance to chemicals. With resins formulated from these diols it should be borne in mind that traces of phenolic groups can interfere with curing.

Bisphenol A

Although *bis(hydroxymethyl)tricyclodecane* [*26896-48-0*] is expensive, it imparts high thermal stability and chemical resistance, with tack-free hardening of uncovered surfaces.

Dibromoneopentyl glycol [*3296-90-0*] is used to reduce combustibility. A disadvantage is that hydrogen bromide readily splits off during polycondensation and attacks the walls of

the reaction vessel. Dibromoneopentyl glycol is therefore seldom used.

N,N-Bis(2-hydroxyethyl)-p-toluidine [*3077-12-1*] is sometimes incorporated into the polyester chain by condensation to obtain resins that cure at normal temperatures with benzoyl peroxide but without an accelerator.

Monomers for Cross-Linking UP Resins. Vinyl, allyl, and acrylic compounds are suitable monomers for the cross-linking of UP resins. They are readily miscible with the resins and their homopolymerization rate does not exceed the copolymerization rate with the unsaturated polyester chain. In most cases low- to medium-viscosity UP resins are required. *Styrene* [*100-42-5*] is by far the most suitable monomer for these products (→ Styrene). The styrene content is normally between 25 and 45 wt %.

The following vinyl compounds are often recommended as alternatives, but are of little practical importance:

α-Methylstyrene [*98-83-9*] is insufficiently reactive. *4-Methylstyrene* [*622-97-9*] would be the most suitable alternative to styrene for technical reasons [6], but has an unpleasant odor and is not produced on an industrial scale.

Vinyltoluene, an isomeric mixture mainly of 4- and 3-methylstyrenes, is not very suitable on account of its low reactivity and unpleasant odor.

Divinylbenzene [*1321-74-0*] is not available in large amounts.

Methyl methacrylate [*80-62-6*] copolymerizes with difficulty with unsaturated polyesters. It is used in combination with styrene, however, to improve weather resistance and to lower the refractive index. The ratio of the refractive index of the resin to that of the glass fiber reinforcement determines the transparency of finished parts such as domelights and light panels.

Diallyl phthalate [*131-17-9*] is used as a cross-linking agent in the production of pourable, solid UP resin molding compositions. The viscosity of diallyl phthalate is too high for liquid UP resins and copolymerization is too slow for curing at room temperature.

Triallyl cyanurate [*101-37-1*] is also a conventional cross-linking agent for solid molding compositions.

3. Production

UP resins are usually produced by batchwise condensation of dicarboxylic acids or anhydrides with diols. Continuous esterification of acid anhydrides and epoxides may, however, also be employed.

Batchwise Condensation. Dicarboxylic acids are esterified with diols at 180 – 230 °C in a nitrogen atmosphere in heatable, coolable reactors while stirring. Esterification is generally performed with a slight excess (up to 10 %) of diols. The water formed in the reaction is distilled off. Passage of nitrogen through the reaction mixture promotes removal of water and increases the esterification rate considerably. The end point of the condensation is determined by measuring the acid number and, possibly, also the hydroxyl number and the viscosity. Commercial UP resins have a mean molecular mass of 2000 – 4000.

The still liquid melt is cooled and then dissolved, while stirring, in styrene in coolable mixers. The styrene contains inhibitors such as hydroquinone or *tert*-butylcatechol (see Chap. 4).

Even if the same raw materials are used, the resin products may differ as regards their processing properties and end properties depending on the amount of excess glycol, the temperature, and reaction conditions.

In the case of raw materials with widely differing esterification rates, two-stage condensation must be used to obtain uniform buildup of the polyester chain and thus favorable end properties. For example, if isophthalic acid and maleic acid are added simultaneously to the reaction vessel, maleic acid is incorporated more quickly into the polyester chain. In the case of isophthalic acid resins, isophthalic acid should therefore first be condensed with glycol in a molar ratio of 1 : 2 to form a bishydroxy ester. Esterification should be continued after adding maleic anhydride.

Azeotropic esterification is important only for certain paint resins. An entraining agent (e.g., toluene or xylene) is added and during condensation the water is distilled off together with the toluene. The toluene is then separated from the water with a dephlegmator and returned to the reactor. At the end of the reaction the toluene must be removed from the resin (e.g., with a thin-film evaporator).

Continuous esterification of acid anhydrides and epoxides is a very elegant, economic method. However, it is limited to the small number of raw materials that are available as anhydrides or epoxides. It cannot, therefore, meet the demands of the polyester processors for different resin types. Thus, for example, the extremely important isophthalic and terephthalic acid resins cannot be produced by this method because the dicarboxylic acids do not form anhydrides. The method is recommended only for producers with very large sales of standard resins.

The raw materials (e.g., maleic anhydride, phthalic anhydride, and propylene oxide) are converted into polyesters by reacting them for ca. 20 min and 200 °C, generally in the presence of catalysts. In contrast to batchwise condensation, no water of reaction is formed.

4. Additives

See also → Plastics, Additives

Inhibitors are used to prevent premature polymerization and to modify the reaction times. The most important are hydroquinone, 1,4-benzoquinone, *tert*-butylpyrocatechol (*tert*-butylcatechol), toluhydroquinone (methylhydroquinone), and 3,4-di-*tert*-butyl-*p*-cresol (3,4-di-*tert*-butyl-4-hydroxytoluene). All these inhibitors have specific effects and are used for different resin types. In some cases they are added prior to condensation, in other cases they are dissolved in styrene and added after condensation.

Optical brighteners are added to slightly yellowish resins for certain uses (e.g., transparent products or white buttons). Blue dyes, which become decolorized during curing, are commonly used as curing indicators.

Commercially available *light stabilizers* (e.g., substituted benzophenones and hydroxyphenyltriazoles) prevent premature yellowing of the hardened resins in sunlight.

Thixotropic agents have to be added to prevent sagging or dripping of the resins when applied to vertical surfaces. Finely dispersed silica is mainly used for this.

Most UP resins have a tacky surface when cured in air. Tackiness can be prevented by adding *skin-forming agents*, generally paraffins. The formation of a paraffin film also reduces styrene emission in pressureless processing. Resins containing such additives are termed "environmentally friendly" or "milieu polyesters".

The additives listed above are generally added to the resin by the resin manufacturer. The following substances are added to the resin by the processor.

Hardened UP resins have a surface resistance of $>10^{13}\,\Omega$. In order to prevent buildup of electrostatic charge, graphite and metal powders can be added as *antistatic agents* to reduce the surface resistance to ca. $10^4\,\Omega$.

Flame retardants include chlorinated paraffins and antimony trioxide. Aluminum hydroxide (hydrated alumina) is employed on a large scale for parts used in the electrical industry that have to be halogen-free (halogens can attack copper contacts and hydrogen chloride may be released during fires).

Both soluble *dyes* and insoluble *pigments* can be used for coloring. Pigments have to be made into a paste in resins or plasticizers before being added.

Fillers include chalk, quartz flour, and quartz sand. The type and amount of filler depend on the final use and desired properties of the resin. Filled resins serve as putties, compression molding compounds, casting compounds, mortars, and concrete. The fillers must be dry so that they do not to affect curing.

Blowing agents are used to produce polyester foams, various additives and systems are used for this (e.g., azodicarbonamide, *tert*-butylhydrazinium chloride and iron(III) chloride).

Thickening agents are required for the production of sheet molding compounds (SMC), and bulk molding compounds (BMC). Magnesium oxide and, in some cases, magnesium and calcium hydroxides are normally used. These

agents are mixed with fillers and used to impregnate glass fibers, thereby converting the molding compound into a highly viscous state.

Low-shrink and low-profile additives are solutions of thermoplastics in styrene and are added to reduce volume shrinkage occurring during curing. Polystyrene, poly(vinyl acetate), poly-(methyl methacrylate), saturated polyesters, cellulose acetobutyrate, and polycaprolactams are usually used. Polyethylene with a particularly low melting point is used to improve the properties of sheet molding compounds. On account of its insolubility it has to be added to the resin batch as a powder immediately before processing.

5. Curing

At normal temperatures UP resins can be cured with peroxides and accelerators. The most important systems include hydroperoxides (e.g., methyl ethyl ketone peroxide, cyclohexanone peroxide, and acetylacetone peroxide) with cobalt octanoate or, in exceptional cases, also vanadium octanoates or naphthenates, as well as benzoyl peroxide (dibenzoyl peroxide) with aromatic amines (e.g., *N,N*-dimethylaniline, *N,N*-diethylaniline, and *N,N*-dimethyl-*p*-toluidine).

Moisture slows down or prevents curing with hydroperoxides and cobalt salts, but does not affect reactions with benzoyl peroxide and amines. Complete curing generally requires heating above the glass transition temperature of the cross-linked polyester. Only completely cured products exhibit optimum mechanical properties and resistance to weathering and chemicals.

At elevated temperatures only peroxides are required for curing, accelerators are unnecessary. Examples include dibenzoyl peroxide above ca. 80 °C, *tert*-butyl 2-ethylperhexanoate above ca. 100 °C, and *tert*-butyl perbenzoate above ca. 120 °C.

UP resins can also be completely cured in a few minutes by exposing them to UV light from high-pressure mercury vapor lamps in the presence of photosensitizers, e.g., benzoin ether [*24650-42-8*] (ω,ω-dimethoxy-ω-phenylacetophenone).

Some acyl phosphine oxide compounds [7] can be used in combination with the aforementioned UV sensitizers to allow curing in normal daylight.

Detailed information about optimum curing systems and reaction conditions for specific uses are given in the data sheets published by resin and reactant manufacturers.

During the transition from the liquid to the solid state, UP resins shrink by 5 – 8 % depending on their double bond content. Compensation of shrinkage by thermoplastics additives is discussed in Chapter 4.

6. Types of UP Resins

Many types of UP resins are available. Selection depends on processing properties and end properties. Processing properties include reactivity, viscosity, and thickening behavior with magnesium oxide. End properties include mechanical behavior, thermal stability, flammability, resistance to chemicals, and color.

Resins may be liquid (low-, medium- or high-viscosity) or solid. Their reactivity may be low, average, or high. A wide range of UP resins can be produced by appropriate choice of the following factors: type and quantity of raw materials, degree of condensation, acid and hydroxyl numbers (and thus the nature of the terminal groups), and the content of cross-linking monomers and other additives. Consequently, comparison or exchange of related resin types from different producers may be difficult.

Standard resins are formulated from inexpensive raw materials and have a wide variety of uses. They can be supplied with or without additives (light stabilizers, thixotropic agents, accelerators, or UV sensitizers).

Elastic grades have a high flexibility and elongation at break due to the incorporation of long-chain monomers, and are generally used in admixture with more brittle types. Some highly elastic grades are used for jointless roof coverings on account of their weather resistance and

high elongation at break of up to 200 % in tensile tests.

Flame-resistant resins generally contain chlorine or bromine in the polyester chain or in added compounds. Flammability can be adjusted to satisfy widely differing regulations and standards by using other additives such as phosphorus compounds, antimony compounds, and aluminum hydroxide.

Resins with a high chemical resistance are mainly synthesized from special raw materials such as isophthalic acid, terephthalic acid, neopentyl glycol, ethoxylated or propoxylated bisphenol A or bis(hydroxymethyl)tricyclodecane. They are used particularly in chemical apparatus (pipes and vessels).

Resins for *sheet molding compounds (SMC) and bulk molding compounds (BMC)* have specially adjusted ratios of acid and hydroxyl numbers and a constant water content. This ensures controlled thickening with magnesium oxide (MgO). Low-shrink and low-profile additives may also be added to the individual types, compatibility depends on the degree of unsaturation [8].

Resins for *fillers and putties* are preaccelerated with aromatic amines. This ensures accurate adjustment of curing with benzoyl peroxide and allows sanding within a short period of time. Rigid and plasticized resins are available for repair putties and light-colored products for marble putties.

Resins for free-flowing *compression molding compounds* are generally supplied monomer-free in powder form to the molding compound producers, who formulate the compounds with cross-linking agents (e.g., diallyl phthalate or triallyl cyanurate) and fillers.

Table 1. Properties of styrene-containing UP resins in the as-supplied state

Property	Test method	Test value
Acid number	DIN 53 402	10 – 30 mg KOH/g
Styrene content	DIN 16 945	25 – 45 %
Viscosity at 25 °C	DIN 53 015	0.2 – 4.5 Pa · s
Density at 20 °C	DIN 51 757	1.07 – 1.3 g/cm^3
Flash point	DIN 51 755	35 °C
Refractive index at 25 °C	DIN 53 491	1.524 – 1.559

Trade Names. Important trade names of UP resins in Europe and the United States include:

Alpolit	Hoechst
Altek	Alpha Corp.
Aropol	Ashland Chemical Corp.
Beetle	BIP
Civic	Neste Oy
Crystic	Scott Bader
Hetron	Ashland Chemical Corp.
Lamellon	DSM
Leguval	Bayer and DSM
Marco	US-Steel Corp.
Norpol	AS Jotun-Group
Norsodyne	Cray Valley
Palatal	BASF
Polylite	Reichhold Chemicals
Roskydal	Bayer
Selectron	PPG Industries
Sniatron	Alusuisse
Sirester	SIR
Torolithe	Routtand S. A.
Trusurf	OCF Fiberglas Corp.
Uralam	Synthetic Resins
Vestopal	Hüls
Viapal	Vianova Kunstharz

Due to company takeovers or mergers and sales of know-how and trade names, assignment of trade names to manufacturers may change.

7. Testing and Properties

A distinction should be made between the properties of UP resins in the as-supplied state (Table 1) and properties after curing (Table 2).

In order to determine the properties in the as-supplied state, simple, rapid tests are desired by producers and customers for quality assurance. Testing is generally carried out by agreement between suppliers and customers according to national standards, but also according to in-house procedures. The resins are often dispatched with test certificates describing the contents of the delivered batch.

Important properties used to characterize the liquid resins in the as-supplied state include the acid number, solids content, viscosity, refractive index, and reactivity. The acid number, solids content, and viscosity can be used to evaluate the degree of condensation and mean molecular mass. Further important properties of liquid resins are color, flash point, and density.

The acid number is measured by titration with potassium hydroxide solution. The solids content can be determined with automatic thermobalances by evaporating the volatile constituents (basically styrene). Viscosity is

checked with rotating-cylinder viscometers, but also by measuring efflux times from temperature-controlled flow cups. The viscosity can be lowered by dilution with styrene or other monomers. The refractive index is measured in refractometers, and is used to monitor the correct composition of the resin.

Table 2. Properties of cured UP resins without fillers or reinforcement fibers (without soft resins)

Property	Test method	Test value
Density at 23 °C	ISO/R 1183	1.20 – 1.40 g/cm^3
Flexural strength	ISO 178	80 – 160 N/mm^2
Outer fiber strain	ISO 178	2 – 7 %
Impact strength	ISO 179 small test bar	6 – 15 kJ/m^2
Tensile strength	ISO/R 527 test specimen 1	40 – 90 N/mm^2
Elongation at break	ISO/R 527 test specimen 1	1.5 – 5 %
Compressive strength	ISO 664	150 – 180 N/mm^2

Comparative tracking indices	IEC Publ. 112	CTI>600
		CTI>600M
Dielectric strength	IEC Publ. 245	35 – 45 kV/mm

The reactivity of UP resins is generally determined by measuring the rise in temperature that occurs during curing. This method is more sensitive than differential scanning calorimetry. The initial temperatures chosen often depend on the subsequent processing temperatures (e.g., room temperature or the temperature of hot compression molds). Measurements differ widely as regards heating bath, vessels, thermocouples, amount of resin, and nature and amount of the reactants. Accurate comparisons of product data sheets published by various manufacturers cannot therefore be made. Examples of measurement setups are given in DIN 16 945.

The thickening of resins for SMC and BMC with magnesium oxide is an important property but is difficult to measure quickly. A future ISO standard will involve accelerated thickening at elevated temperature, and allows conclusions to be made about thickening behavior at room temperature. This test is satisfactory for resin processors, but resins with the same results may behave differently when tested under normal thickening conditions at 25 °C.

In most cases cured UP resins are relatively brittle, addition of fillers and reinforcing materials (e.g., glass fibers) is required to obtain technically useful properties. Nevertheless, cured UP resins must be tested in the pure state. Production of test specimens requires care and experience because factors such as internal stress arising during curing can falsify the results. Mechanical, thermal, and electrical properties are measured (Table 2). The tensile strength, elongation at break, and thermal stability are particularly important for comparing the performance of different resins.

8. Uses and Economic Aspects

UP resins are only used without fillers or reinforcing agents in small amounts for embedding decorative objects, in furniture lacquers, adhesives, paints (→ Paints and Coatings, Chap. 2.8.) and casting resins (impregnating resins) for insulating electrical equipment (→ Insulation, Electric).

The majority of UP resins are reinforced with glass fibers which impart high strength and rigidity to molded parts. Natural fibers (e.g., jute) and synthetic fibers are also used in elastic molded parts.

Casting compounds, putties (→ Paints and Coatings, Chap. 2.8.), and UP resin concrete are produced using fillers with different particle sizes and compositions.

The most important uses of UP resins follow:

Automobile Construction. Parts for special-order vehicles, caravans, and agricultural vehicles are produced by hand from glass-fiber-reinforced UP resins. Flat sheets and panels for truck superstructures and containers are pro-

duced industrially in continuous laminating processes. Body parts for automobiles and commercial vehicles are produced from preimpregnated SMC.

On account of their outstanding resistance and impact strength behavior, pressed parts made from UP resins reinforced with natural or synthetic fibers are employed in car interior fittings, engine compartments, and vehicle underbodies; they have gained a considerable market share. Filled UP resins are used as automobile repair putties.

Building Industry. The use of light panels made of glass-fiber-reinforced UP resins has greatly declined. UP resins with glass fiber reinforcement are used for domelight crowns, facade elements, cellar window frames, and light shafts made from SMC. Beacons, chimneys, and large aerials are wound from UP resins and glass fibers. Highly elastic casting compounds are used for flat roof coverings. Drainage systems with channels, catch basins, and gasoline separators are produced industrially from polyester concrete. Imitation marble and onyx can be produced from UP resins, colorants, and chalk (marble) or aluminum oxyhydrate (onyx); they are used to produce inexpensive, high-quality sanitary ware.

Electrical Industry. The electrical industry is still a main customer for molded parts made from SMC and BMC. Examples include cable distribution cupboards and switching cupboards, skirting boards for lamps, multiway connectors, switch covers, and clamping sleeves. Coils and windings are impregnated with UP resins.

Pipes, Vessels, and Apparatus. Cylindrical molded components reinforced with glass fibers for the chemical industry and oil transportation are fabricated in winding and centrifugal processes from chemically resistant resins whose chemical resistance is appropriate for the intended use. Glass-fiber-reinforced UP resins are also used for fertilizer and fodder silos and cooling towers.

Boat and Shipbuilding. Glass-fiber-reinforced UP resins have long been used for building sports, life-saving, and fishing boats. Larger vessels (e.g., 50-m long minesweepers with 30-mm thick sides) are now also being built from this material.

Miscellaneous Uses. Other molded parts made from glass-fiber-reinforced UP resins include machinery covers and casings, sports equipment, toys, garden furniture, and traffic signs. Important areas of use of nonreinforced UP resins include buttons, buckles, fashion accessories, and furniture finishings.

Economic Aspects. In 1988 ca. 1.3×10^6 t of UP resins were consumed worldwide.

Following a fall in consumption as a result of the oil crises at the end of the 1970s and subsequent stagnation, polyester resins experienced an increase in consumption. This was primarily due to increased use in the automobile industry, especially in compression molding and resin transfer molding.

Consumption according to areas of use is listed in Table 3. The apparent excess capacities in this table are somewhat misleading because they include alkyd resin capacities for the paint sector. The capacity of the UP resin manufacturers is fully utilized and an expansion in capacity can be expected in the next few years.

9. Occupational Health and Environmental Aspects [9]

Toxicological and environmental aspects of unsaturated polyester resins are principally determined by the properties of styrene (→ Styrene). Styrene is a liquid with a relatively high vapor pressure which means that there may be considerable emissions, particularly when polyesters are processed in open molds.

Irritation of the eyes and mucous membranes of the upper respiratory tract is observed and depends on the exposure period and concentration of styrene in the inspired air. Tiredness, loss of concentration, and similar symptoms have been reported at styrene exposure levels above 100 ppm at the workplace.

Styrene and styrene-containing UP resins were classified in 1988 by the EC as "slightly hazardous" with the danger symbol x_n, R-phrase 10 inflammatory, R-phrase 20 health hazard if inhaled, and R-phrase 36/38 eye and skin

Table 3. International distribution of the areas of use for UP resins (10^3 t)

	United States	Western Europe	Japan
Building and construction	241	125	74
Automobile construction	50	78	9
Pipes and vessels	62	61	67
Boats and shipbuilding	155	55	23
Electrical industry	13	28	9
Paints and other nonreinforced products	68	30	30
Miscellaneous uses	31	73	18
Total consumption	620	450	230
of which			
BMC/SMC ∗	64	58	58
Polymer concrete (in building and construction)	62	36	16
Production capacity	800	540	300

∗ BMC=bulk molding compounds; SMC=sheet molding compounds.

irritant. A grading with the R-phrase 45 "Can cause cancer" was specifically excluded.

In 1989 in the United States, styrene was classed by OSHA as not carcinogenic, and was included in the category "Avoidance of narcosis". The TLV-TWA value was reduced from 100 ppm to 50 ppm.

In Germany the MAK value was reduced from 100 ppm to 20 ppm in 1987 on account of reported neurotoxic effects. It was announced that the carcinogenic effects of styrene would be reexamined.

Maximum workplace concentrations for various countries follow (ppm):

Austria	200
Belgium	50
Commonwealth of Independent States	1.2
Former Czechoslovakia	47
Denmark	25
Finland	20
France	50
Germany	20
Italy	50
Japan	50
Netherlands	100
Norway	50
Poland	12
Sweden	20
Switzerland	50
United Kingdom	100
United States	50

In many countries these concentrations will probably be lowered in the near future.

The observance of low maximum workplace concentrations does not present any particular problem in the production of styrene, polystyrene, and styrene copolymers nor in the processing of polystyrene and styrene copolymers. In UP resin processing, however, it is often almost impossible to satisfy this requirement.

Styrene emissions can be considerably reduced by ventilation devices at the workplace, by using "environmentally friendly resins" that contain a skin-forming agent such as paraffins (Chap. 4), or by completely enclosing automatically operating plants. Statutory regulations (e.g., TA-Luft in Germany) impose limits on the discharge of evaporated styrene and waste-gas treatment plants are necessary if fairly high levels of emissions are reached (e.g., >100 mg/m^3 in TA-Luft).

Prolonged exposure of the skin to liquid UP resins often leads to irritation, and particular care must be taken when working with the peroxides used as curing agents on account of their corrosive effect. Goggles should always be worn to protect the eyes when handling peroxides.

UP resins are flammable and hazard classifications differ in individual countries. The content of volatile monomers (styrene), the flash point, and the viscosity of the resins are usually decisive factors. Details are given in the manufacturers' safety data sheets.

Liquid UP resins containing styrene as crosslinking agent and must not pass into the ground water. Relevant statutory regulations governing the storage and transportation of UP resins must be strictly observed. Storage tanks for UP resins should be installed in catchment basins to trap any leakages or escaping product.

1. Introduction

Classification. Polyesters are defined as all polymers which contain repeating units of the ester group

in the polymer chain. Polyesters are generally produced by condensation of polyfunctional carboxylic acids (or their derivatives) with polyfunctional alcohols. Other methods of production include polycondensation of hydroxycarboxylic acids and polymerization of cyclic esters (e.g., lactones).

Polyesters with widely varying properties can be produced depending on the starting materials:

1) High molecular mass linear polyesters (M_r >10 000) are produced from difunctional alcohols and dicarboxylic acids (or their derivatives, e.g., diesters or dichlorides) or from polymerizable lactones. They can be processed thermoplastically to molding materials (*thermoplastic polyesters*, Chap. 3). The term thermoplastic

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a21_227

polyesters also includes polycarbonates, see → Polycarbonates.

2) Low molecular mass polyesters ($M_r \leq 10\,000$) from saturated aliphatic or aromatic dicarboxylic acids and difunctional or mixtures of di- and trifunctional alcohols are linear or slightly branched *intermediates for polyurethanes* (see Chap. 2).
3) Low molecular mass polyesters ($M_r \leq 10\,000$) from di-, tri-, and polyfunctional alcohols and polyfunctional, usually aromatic carboxylic acids or saturated or unsaturated fatty acids are classified as *alkyd resins*, see → Alkyd Resins.
4) *Unsaturated polyesters* are polyesters which can copolymerize with unsaturated compounds and are formed from polyfunctional alcohols and polyfunctional unsaturated carboxylic acids. After copolymerization with monomers such as styrene they can also be classified as thermosets, see →Polyester Resins, Unsaturated.

2. Polyesters as Intermediates for Polyurethanes

In 1937 O. Bayer developed an addition polymerization method for the synthesis of polyurethanes that was based on the reaction of diisocyanates with polyols [1]. Hydroxy-functional polyesters were soon introduced as reactants. The only highly branched polyesters known at that time were based on aromatic dicarboxylic acids, and they resulted in hard, highly cross-linked products that were processed in coatings and molding compounds [2]. In 1942 H. Pinten treated moderately branched aliphatic hydroxypolyesters with a diisocyanate and obtained a rubbery-elastic material ("I-Gummi") [3]. Systematic study of the reactions of linear and moderately branched hydroxypolyesters with excess diisocyanates, and subsequent treatment of these intermediates with water, diols, diamines, and other compounds containing reactive hydrogens, resulted in a wide range of polymers displaying advantageous properties (e.g., thermosets, thermoplastics, cast elastomers, hard and soft foams, molding compounds, hard and flexible coatings). Polyurethanes came to be known as "tailor-made polymers" [4], [5]. This diversity was partly a result of great flexibility with respect to starting materials, mean molecular mass, and mean functionality.

A broad spectrum of hydroxypolyesters with mean molecular masses between 400 and 6000, hydroxyl numbers of 28 – 300 mg KOH/g, and acid values generally under 1 mg KOH/g are employed as intermediates in the manufacture of polyurethanes. Highly branched polyesters, made largely from aromatic or hydroaromatic dicarboxylic acids, find use as binders for polyurethane coatings (DD coatings, Bayer), → Paints and Coatings[6].

The present review is limited to a discussion of linear and moderately branched hydroxypolyesters derived from aliphatic starting materials.

2.1. Raw Materials

Adipic acid is most commonly employed as the acidic component. Other dicarboxylic acids such as oxalic, succinic, and glutaric acid are of lesser importance because the resulting polyesters exhibit lower stability toward hydrolysis. Higher molecular mass aliphatic carboxylic acids (azelaic acid, sebacic acid) are economically unattractive. "Dimeric acids" [7], produced by the dimerization of unsaturated plant fatty acids and hydroxy-functional monocarboxylic acids, find application in special situations. The hydroxy-functional acid dimers afford the corresponding polyesters [8] by self-condensation onto a starter diol. Aromatic dicarboxylic acids such as phthalic acid (in the form of the anhydride), isophthalic acid, and terephthalic acid are sometimes added as modifiers. Typical diol components are ethylene glycol, diethylene glycol, 1,2-propanediol, 1,3-butanediol, 1,4-butanediol, neopentyl glycol, and 1,6-hexanediol. Glycerol, trimethylolethane, trimethylolpropane, and hexanetriol are employed to obtain branched polymers. Developments in the synthesis of hydroxypolyesters include the use of raw materials such as ε-caprolactone, which affords polycaprolactone [9] via ring-opening polymerization on a starter polyol. Oligo- or polyethers can also be incorporated into the polymer chain, leading to the corresponding etheresters [10].

2.2. Production

2.2.1. General Information

The only currently economic method for the production of polyesters is direct esterification of dicarboxylic acids with diols [11]. Since esterification is a reversible equilibrium reaction, the process can only be driven to completion if the resulting water of condensation is continuously removed. Polyesterification represents an example of *condensation polymerization*. Not only are monomeric units added to the growing chains, but individual chains also react with one other because they may have both carboxyl and hydroxyl terminal groups. The esterification conditions also permit constant transesterification within the chain itself. Consequently, polyesters exhibit relatively broad molar mass distributions, which can be calculated using the Schulz–Flory method [12], [13]. Transesterification also accounts for the fact that, if more than two starting materials are employed, these become incorporated into the polyesters in a statistical way regardless of their time of introduction.

The esterification of a dicarboxylic acid with a diol represents a higher-order reaction. In the absence of an added catalyst, and if the reverse reaction is prevented by removal of the resulting water, the kinetics of the reaction can be described as third order [14], [15] because the acidic groups themselves exert a catalytic effect on the reaction:

$$\text{Reaction rate} = k \cdot [\text{OH}] \cdot [\text{COOH}]^2$$

When an esterification catalyst is utilized, its influence becomes dominant and esterification exhibits second-order kinetics. Esterification is catalyzed by acids, bases, and transition-metal compounds. However, the commercial use of catalysts is limited because all catalysts tend to have undesirable effects on subsequent polyurethane reactions. In the case of polyesters that are used in reactions where traces of catalyst do not interfere, synthesis is catalyzed with low concentrations (ppm) of compounds of titanium, tin, or antimony. The appropriate starting ratios for the synthesis of a given hydroxypolyester can, in theory, be calculated from the desired number-average molecular mass (M_n), which can in turn be determined from the hydroxyl number.

Given the simplified formula

a linear polymer would result from n mol of dicarboxylic acid (HOOC−R′−COOH) and n+1 mol of diol (HO−R−OH). The degree of polycondensation, n, is calculated as follows:

$$n = \frac{M\,(\text{polyester}) - M\,(\text{diol})}{M\,(\text{dicarboxylic acid}) + M\,(\text{diol}) - 2M\,(\text{water})}$$

Losses of diol accompanying the removal of water of condensation and as a consequence of side reactions (formation of ethers and aldehydes) usually require the addition of an empirically determined excess of diol which depends upon the type of diol and the reaction conditions.

The first phase of the esterification is conducted under an inert atmosphere (nitrogen, carbon dioxide) and the water of condensation is removed rapidly by distillation through a column at >130 °C. Once an acid value of about 30 has been reached, the reaction must be accelerated in a second phase by facilitating the removal of water from the esterification equilibrium. This is done by application of a vacuum (vacuum-melt method), introduction of a carrier gas (usually carbon dioxide), or recirculation of an entrainer such as toluene or xylene (azeotropic distillation). The last approach is not applicable when the diol component is ethylene glycol or 1,2-propanediol, which themselves form azeotropic mixtures with the entrainers.

A low acid value (<1 mg KOH/g) is desired. This means that the reaction mixture tends to become highly depleted in one reactant toward the end of the reaction, greatly reducing the rate. This second phase of polyester synthesis therefore requires a large fraction of the overall reaction time (e.g., 20 of 30 h).

2.2.2. Industrial Production

Polyesters are produced industrially either batchwise or continuously according to a variety of methods. The vacuum-melt and the purge-gas-melt methods are preferred, the azeotropic method finds only limited application.

Batchwise Vacuum-Melt Method [16]. The apparatus constitutes a closed system, comprising a stirred-tank reactor equipped with an anchor agitator, a distillation column, a condensor, a receiver, and a vacuum pump. The starting materials are heated in the reactor, with stirring but in the absence of air. Heat is provided by electrical energy, high-pressure steam, or a heat-transfer medium. In the first phase of the reaction the temperature is held between 125 and 220 °C under ambient pressure and ca. 90 % of the resulting water is removed by distillation. A mixture of oligoesters is produced which is immediately condensed to polyester in the second reaction phase at 170 – 230 °C and with stepwise reduction of the pressure to 0.005 bar. Residual water of reaction is distilled from the mixture, together with excess diol and minor byproducts such as low molecular mass aldehydes and ketones (present in ppm amounts relative to the polyester). The process is monitored constantly by measuring the acid value, the hydroxyl number, and the viscosity.

Example of the preparation of a polyester with an average molecular mass of 2000 from ethylene glycol and adipic acid. A mixture of 86.8 kmol of adipic acid and 95.6 kmol of ethylene glycol, including an empirically determined excess of 1.1 kmol ethylene glycol, is heated with stirring under nitrogen to 130 °C. Once distillation begins the temperature of the reaction mixture is raised to 200 °C over the course of 10 h. During this period 156 kmol of water of reaction is distilled into the receiver. When distillation is complete, the acid value of the reaction mixture is ca. 55 mg KOH/g. The pressure in the apparatus is subsequently reduced in stages to 0.01 bar at constant temperature over a period of 15 h. During this period the remainder of the water of reaction is distilled off, along with excess ethylene glycol and byproducts. The reaction mixture has the following properties: hydroxyl number, 55.5; acid value, 0.7; viscosity, 0.515 Pa · s at 75 °C; water content, 0.02 wt %. After pressure equilization with nitrogen and cooling to 110 °C, the polyester product (7.7 kmol) is transferred to a storage tank.

Purge-Gas – Melt Method [17]. This process differs from the vacuum-melt method in that during the second phase of reaction the distillable products are removed by passage of an inert gas (N_2, CO_2) through the mixture rather than by lowering of the pressure. This method increases the loss of diol, a fact that must be taken into account in the raw material calculations. The apparatus must also be suitably adapted: the reactor is equipped with a gas inlet and the distillation column is replaced by a simple distillation tube. A vacuum pump is not required.

Azeotropic Method [18]. This process is conducted at atmospheric pressure in the presence of an inert solvent (e.g., toluene or xylene) which entrains and removes the water of reaction. A vacuum-melt apparatus can be adapted to the azeotropic method by including facilities for removal and continuous recycling of the entrainer solvent. Lower reaction temperatures (125 – 190 °C) are used and permit polyester to be produced under milder conditions. Solvent residues in the final product are removed under vacuum.

Wastewater and Exhaust Air. Both the water of reaction and the process exhaust air contain excess diols and reaction byproducts which are biodegradable in dilute aqueous solution. The processes do not therefore present environmental problems if an exhaust air purifier and a biological water treatment system are employed.

Construction Materials. The materials used for constructing the equipment must satisfy a variety of demands. High resistance to corrosion is essential with respect to the acidic reaction medium and the distillates to prevent contamination of the polyester with traces of metal. Moreover, stress may also arise in the reactor materials due to the high reaction temperatures. These requirements are best met by highly alloyed austenitic chromium – nickel – molybdenum steels, for example V 4 A steel (DIN 1.4571).

The material requirements posed by the raw materials and hydroxypolyester products are less severe. Stainless steel (V 4 A, V 2 A), pure aluminum, $AlMg_3$ alloy, and in special cases even unalloyed steel can therefore be used for pipes and containers for storage and transport.

2.3. Quality Specifications and Testing

Since hydroxypolyesters are subjected to further processing to polyurethanes, they must satisfy stringent quality criteria that can only be obtained through a high degree of product standardization. The most important input data for the polyurethane reaction include the hydroxyl number (DIN 53 240), acid value (DIN 53 402), water content (DIN 53 979), color number (iodine number, DIN 6162; Hazen/APHA, DIN 53 404), and viscosity (DIN 53 015), and are fixed within narrow tolerances for each type of polyester. Individual products often have additional quality criteria that depend on further processing.

The acid value is a measure of the content of terminal carboxyl groups in the polymer and is especially important. A minimum acid value is preferred because terminal carboxyl groups react with isocyanates much more slowly than hydroxyl groups, and can therefore lead to chain termination during polyaddition. Furthermore, the reaction of carboxyl groups with isocyanates produces amide functions and carbon dioxide, which can result in undesirable bubble formation in the polyurethane. Finally, residual acid in a polyester has negative effects on catalysis of the polyurethane reaction and the stability of the polyurethane product toward hydrolysis. Consequently, an acid value limit is mandatory for polyesters (generally <1 mg KOH/g, but often <0.5 mg KOH/g).

The presence of even trace amounts (ppm levels) of metals, acids or bases, fats, silicone oils, and other surface-active agents in polyesters must be avoided. Such impurities can originate from the starting materials or the processing equipment; their removal is extremely difficult, if not impossible. Consequently, both starting materials and apparatus must be subjected to rigid standards. The analytical data cited in Section 3.1 for the thermoplastic polyester raw materials must be regarded as minimum standards.

Manufacturers utilize the test methods already described, and other specially developed tests for product and process quality control. An applications test is often conducted for final quality assessment.

2.4. Properties

Physical Properties. The diverse applications of polyester-polyurethanes require a wide variety of starting materials. Pure polyadipates of ethylene glycol, 1,4-butanediol, and 1,6-hexanediol are waxy crystalline substances with softening points around 40 – 50 °C. Their crystallinity helps to provide the polyurethane products with outstanding physical characteristics, especially with regard to elasticity, tensile strength, and notch resistance. In some application areas, however, a tendency to harden at low temperatures or as a result of stress (crystallization of elongation) is problematic.

Polyesters made from mixtures of the aforementioned diols, alone or in combination with other diols, can be advantageous in such cases, and are either liquid or greasy at room temperature. 1,2-Propanediol, 1,3-butanediol, diethylene glycol, and neopentyl glycol afford liquid polyadipates.

Due to their broad molecular mass distributions (Schulz–Flory distribution) [12], [13], the polyesters have a relatively high viscosity (e.g., ca. 600 mPa · s at 75 °C and a mean molecular mass of 2000). Densities range between 1.1 and 1.5 g/cm^3. The flash points (DIN 51 758) lie above 200 °C, and the ignition points (DIN 51 794) above 400 °C. Polyesters are relatively soluble in common organic solvents, including acetone, ethyl acetate, and toluene.

Chemical Properties. Terminal hydroxyl groups are largely responsible for the chemical properties of the polyesters, which undergo reactions typical of alcohols. The most important reaction from an applications standpoint is the facile, quantitative addition of hydroxyl groups to the isocyanate groups of di- and polyisocyanates, which affords segmented, high molecular mass polyester-polyurethanes (→ Polyurethanes).

The polyesters exhibit a certain degree of sensitivity toward hydrolysis, and newly formed acidic groups have an autocatalytic effect. The rate of hydrolysis is also increased by the same compounds that catalyze esterification. Resistance to hydrolysis is a function of polyester structure and increases with increasing hydrophobic character and with decreasing ester-group content [16]. Polyesters derived from

long-chain diols and dicarboxylic acids are more stable than those based on short-chain starting materials. Diethylene glycol polyesters exhibit only marginal resistance to hydrolysis because of the hydrophilic effect of their ether groups. During further processing acid acceptors (e.g., carbodiimide, epoxides) are often added as hydrolysis stabilizers.

2.5. Storage and Transportation

During storage and transportation of polyesters, exposure to moisture and temperatures above 120 °C must be prevented to avoid undesirable effects during polyurethane production. The products are either stored in sealed, air-tight drums at ambient temperature or in heated, insulated containers under nitrogen at 70 – 110 °C. As liquids they are transported in barrels or in heatable, insulated bulk containers; as solids they are transported in drums.

The construction materials mentioned in Section 2.2.2 are generally utilized for storage and transport vessels; barrels are usually constructed from tin-free steel. Turbidity is sometimes observed in polyesters that are liquid at ambient temperature but have been stored for long periods of time at low temperature; this can be alleviated without affecting the quality of the product by heating the polyester briefly to 80 °C.

Recommendations regarding storage and transport conditions for polyesters are provided by manufacturers. Handling of polyesters presents no significant hazards – a consequence of their chemical characteristics. Spilled material is best treated by mixing it with sand and then sending it to an approved waste disposal site, or by burning it in an appropriate incinerator.

2.6. Uses and Economic Aspects

Hydroxypolyesters are sometimes reacted either alone or in combination with diols or diamines to give segmented polyurethanes, which are marketed as aqueous dispersions, solutions, or as powders that are thermoplastically processable or soluble in special solvents (→ Fibers, 4. Synthetic Organic, Chap. 3.; → Polyurethanes). In other cases they are combined on site with polyisocyanates and various additives to form soft to hard foams, elastomers, adhesives, flexible coatings, and joint fillers.

The polyesters described above are marketed by a number of firms; individual product types are further characterized by appended letters and/or numerical indices. Examples of trade names include:

Baycoll, Bayflex, Baygal, Baytec, Baytherm	Bayer
Crestapol	Scott Bader
Daltogel, Daltolac, Daltorez	ICI
Desmophen	Bayer
Diorez	Briggs and Townsend
Estolan	Lancro Chemicals
Fomrez	Witco Chem. Corp.
Lumitol/Elastophen	BASF
Multron/Multrathane	Miles Inc. (formerly Mobay Chem. Corp.)
Nippolan	Nippoly
Polyesteralkohol/Systol	BASF Schwarzheide GmbH
Vulkollan	Bayer

Estimated production capacities in 1983 were (in 10^3 t/a):

Federal Republic of Germany	89
German Democratic Republic and Poland	15
EC	188
United States	44
Japan	21
World	277

Worldwide consumption in 1983 was estimated at ca. 200 000 t.

3. Thermoplastic Polyesters

[19][20][21][22][23][24][25]

The history of thermoplastic polyesters (see also → Fibers, 4. Synthetic Organic, Chap. 2.) goes back to 1929 with the pioneering work of Carothers. The first thermoplastically processible polyesters synthesized from adipic acid and ethylene glycol were described by him in 1932. Polyesters only became of industrial interest in 1941, with the synthesis of high melting point products based on terephthalic acid.

The rapid industrial development of polyesters after World War II was initially restricted to polyester fibers based on poly(ethylene terephthalate) [*25038-59-9*] (PETP), poly(oxy-1,2-ethanediyloxycarbonyl-1,4-phenylenecarbonyl). A polyester based on poly(1,4-dimethylenecyclohexane terephthalate) [*25135-20-0*],

PDCT, occupies a special position (see also → Fibers, 4. Synthetic Organic, Chap. 2.4.2.).

Poly(ethylene terephthalate) was subsequently also used in the production of films (see also → Films, Chap. 6.8.).

Thermoplastic polyesters were first employed as construction materials in 1966 [26], and were initially based on poly(ethylene terephthalate). In 1970 the more readily processible poly(butylene terephthalate) [*24968-12-5*] (PBT), poly-(tetramethylene terephthalate), poly(oxy-1,4-butanediyloxycarbonyl-1,4-phenylenecarbonyl) was introduced onto the market.

A short time later these homopolyesters were supplemented by a series of thermoplastic copolyesters which are suitable for specific areas of application due to their special properties [27]. These copolyesters include polyetherester block copolymers as thermoplastic elastomers; copolyesters based on 1,4-cyclohexanedimethanol for hard, glass-clear injection molded articles; and other thermoplastic copolyesters of varying composition for powder coatings, paint binders (→ Paints and Coatings, Chap. 2.7.), and hotmelt adhesives.

A new class of fully aromatic thermoplastic polyesters has been developed – liquid crystalline polyesters [28], [29]. These polymers have aroused great interest on account of their outstanding mechanical and thermal properties. Two such products are commercially available, one being synthesized from 4-hydroxybenzoic acid and 6-hydroxy-2-naphthoic acid, and the other from 4-hydroxybenzoic acid, terephthalic acid, and 4,4′-dihydroxybiphenyl.

3.1. Raw Materials

Thermoplastic polyesters are generally produced from dicarboxylic acids and dihydric alcohols. The most common raw materials follow:

Dicarboxylic acids (and derivatives)
Dimethyl terephthalate [*120-61-6*]
Terephthalic acid [*100-21-0*]
Dimethyl isophthalate [*1459-93-4*]
Isophthalic acid [*121-91-5*]
Dimethyl adipate [*627-93-0*]
Adipic acid [*124-04-9*]
Azelaic acid [*123-99-9*]
Sebacic acid [*111-20-6*]
Dodecanoic diacid [*693-23-2*]
1,4-Cyclohexane dicarboxylic acid [*1076-97-7*]
Dimethyl-1,4-cyclohexane dicarboxylate ester [*94-60-0*]

Hydroxycarboxylic acids and lactones
4-Hydroxybenzoic acid [*99-96-7*]
6-Hydroxy-2-naphthoic acid [*16712-64-4*]
Pivalolactone [*1955-45-9*]
ε-Caprolactone [*502-44-3*]

Dihydric alcohols and bisphenols
Ethylene glycol [*107-21-1*]
1,2-Propanediol [*57-55-6*]
1,3-Propanediol [*504-63-2*]
1,4-Butanediol [*110-63-4*]
1,4-Cyclohexanedimethanol [*105-08-8*]
2,2-Dimethyl-1,3-propanediol [*126-30-7*]
1,6-Hexanediol [*629-11-8*]
Poly(tetrahydrofurandiol) [*9040-43-1*]
4,4′-Dihydroxy-1,1′-biphenyl [*92-88-6*]
1,4-Hydroquinone [*123-31-9*]

Terephthalic acid is by far the most important dicarboxylic acid. This compound was previously difficult to obtain in sufficiently pure form, dimethyl esters of dicarboxylic acids were therefore mainly used as raw materials. Lactones, hydroxycarboxylic acids, and bisphenols are of lesser importance.

Particularly stringent requirements are placed on the purity of the raw materials because impurities can either interfere with polycondensation via chain termination or branching (e.g., mono- or polyfunctional compounds) or can lead to undesirable secondary reactions and discoloration under the high reaction temperatures. These requirements apply to polyesters used as starting material for fibers, but particularly to the plastics sector where polyesters with substantially higher molecular masses are needed.

Analytical requirements for the four most important raw materials are as follows:

Dimethyl Terephthalate (DMT). For production and properties see → Terephthalic Acid and Dimethylterephthalates.

Purity (GC analysis)	>99.9 %
Solidification point (min.)	140.63 °C
Saponification value	577.8 mg KOH/g
Acid value (max.)	0.03 mg KOH/g
Acid value after 4 h at 175 °C (max.)	0.06 mg KOH/g
Color of the melt after 24 h at 170 °C (max.)	10 (Hazen number)
Color in H_2SO_4 (max.)	10 APHA
Fe content (X-ray fluorescence) (max.)	1 ppm
Nitro groups and nitroso groups should also be absent	

Terephthalic Acid (TA). For production and properties, see → Terephthalic Acid and Dimethylterephthalates. The purity of "polymer grade" terephthalic acid must satisfy appropriate requirements for the production of fibers, films, and molding compounds. As a rule terephthalic acid is available with the following specifications:

Acid value	675 ± 2 mg KOH/g
Ash content (max.)	15 ppm
Metals (atomic absorption) (max.)	10 ppm
of which Fe (max.)	2 ppm
Co, Mo, Ni, Ti, Mg (max.)	1 ppm
Ca, Al, Na, K (max.)	2 ppm
4-Carboxybenzaldehyde (polarography) (max.)	25 ppm
Water content (Karl Fischer) (max.)	0.5 %
Color in 5 % dimethylformamide (max.)	10 APHA

Under certain conditions (absence of fluorenone structures, maintenance of a defined color index) the 4-carboxybenzaldehyde content can reach 200 ppm without impairing the polyester quality [30].

Ethylene Glycol. For production and properties, see → Ethylene Glycol.

Relative density d_{20}^{20}	1.1151 – 1.1156
Boiling point range	196 – 200 °C
Solidification point	−11 to −13 °C
Acid content as acetic acid (max.)	0.005 %
Fe content (max.)	0.07 ppm
Chlorine compounds	none
Diethylene glycol content (max.)	0.08 %
Water content (max.)	0.08 %
Ash content (max.)	0.005 g/100 mL
Acetaldehyde content (max.)	30 ppm
Color index after 24 h at 170 °C	<10 (Hazen number)
UV transparency at m	
220 μ	70 %
275 µm	90 %
350 µm	95 %

1,4-Butanediol. For production and properties, see → Butanediols, Butenediol, and Butynediol, Chap. 1.3.

Purity (GC analysis) (min.)	99.3 %
Water content (max.)	0.05 %
Solidification point (min.)	19.5 °C
Color index (max.)	10 APHA
Ash content	0

3.2. Production

3.2.1. General Principles

Two-Stage Process. Generally, thermoplastic polyesters are produced in two stages. In the first stage a polyester precondensate (M_n 100 – 2000, depending on the molar ratio of the starting compounds) with the formula

$$HO-Y-O\,(OC-X-COO-Y-O)_x\,H,\ x \approx 1-10$$

is produced by transesterification of dicarboxylic diesters or by esterification of the dicarboxylic acid HOOC−X−COOH with excess dihydric alcohol HO−Y−OH. The precondensate then reacts in a second step (i.e., polycondensation) with the elimination of dihydric alcohol to form high molecular mass polyesters (M_n > 10 000) of the formula:

$$HO-Y-O\,(OC-X-COO-Y-O)_y\,H,\ y \geq 100$$

Transesterification and esterification are equilibrium reactions that are accelerated by catalysts. The reactions are continuously displaced towards the polyester precondensate by removing the more volatile alcohol or water.

Polycondensation is also an equilibrium reaction, which is shifted towards the high molecular mass polyester by constant removal of the eliminated diol or water (application of a vacuum or purging with an inert gas), and is accelerated by catalysts. The higher the desired molecular mass of the polyester, the more severe are the conditions required to remove the diol and water. Polycondensation is a step-growth reaction (of the type A – A+B – B=diol + dicarboxylic acid or A – B=hydroxycarboxylic acid), which leads to nonuniform end products. The molecular mass distribution can be calculated from the

molar ratio of diol to dicarboxylic acid and/or from the conversion p [31]. With a stoichiometric ratio of the A and B groups, the mass fraction W_x of the degree of polycondensation x can be specified as a function of the conversion p [32]:

$$W_x = \frac{(M_L + M_U x)}{[M_U + M_L (1-p)]} \, p^{x-1} (1-p)^2$$

M_L and M_U denote the molecular masses of the leaving molecules L and basic units U, respectively. For negligibly small molecular masses of the leaving molecules ($M_L/M_U \rightarrow 0$) or as an approximation for high conversion rates ($p \rightarrow 1$), the equation transforms to the Schulz–Flory distribution function

$$W_x = x p^{x-1} (1-p)^2$$

Introduction of the mean degree of polycondensation $\bar{P}_n = 1/(1-p)$ gives

$$W_x = \frac{x}{\bar{P}_n^2} \left(1 - \frac{1}{\bar{P}_n}\right)^{x-1}$$

The relationship $\bar{P}_n = 1/(1-p)$ clearly shows that a minimum degree of polymerization of 100 can only be achieved with conversions of $> 99\,\%$ (p=0.99).

The kinetics of esterification, transesterification, and polycondensation [33–40] have been investigated in great detail. See also → Polymerization Processes, Chap. 1., → Polymerization Processes, Chap. 2. In general, polycondensation is regarded as a second-order reaction [41], [42], with an activation energy that depends strongly on the catalyst system (PETP: uncatalyzed 96.6 kJ/mol [41], catalysis with manganese acetate 40.8 kJ/mol [42]).

Other Processes. In addition to the conventional two-stage process for producing linear thermoplastic polyesters, many other processes are used with other starting compounds. Addition of ethylene oxide to dicarboxylic acids gives bis(2-hydroxyethyl) esters. In analogy with the previously described esterification and transesterification products, these esters undergo polycondensation with the elimination of ethylene glycol [43].

Fully aromatic polyesters with a high melting point are produced by interfacial polycondensation of dicarboxylic dichlorides with bisphenols in the presence of bases and with elimination of hydrogen chloride [44]. Dicarboxylic acids also react with diesters (preferably acetates) of dihydric alcohols with the elimination of acid [45].

The esterification of an anhydride with a dihydric alcohol or the transesterification of anhydrides with epoxides yields linear polyesters [46], [47].

A special process for producing high molecular mass thermoplastic polyesters involves the polymerization of lactones in the presence of organometallic compounds [48].

Secondary Reactions [49–51]. In all methods for producing linear thermoplastic polyesters, secondary reactions that occur during polycondensation can alter the stoichiometric ratio and thus terminate polycondensation or confer undesirable properties on the end product.

The most important secondary reactions include:

1) Ether formation to produce diethylene glycol units (Y=C_2H_4)

2) Dehydration of ethylene glycol to form acetaldehyde, or of 1,4-butanediol to form tetrahydrofuran

3) Ester pyrolysis which in the case of PETP, for example, produces carboxyl groups (poorer resistance to hydrolysis) and olefins (discoloration):

4) Ring formation between two adjacent carboxyl groups (particularly pronounced in adipic acid):

3.2.2. Production of Poly(Ethylene Terephthalate) from Dimethyl Terephthalate

Poly(ethylene terephthalate) (PETP) is produced industrially both batchwise and continuously. The apparatus used for these processes is also suitable for the production of other thermoplastic polyesters. For the sake of simplicity, however, the batchwise production of PETP is discussed here. Separate vessels are often used to melt the starting compounds and for the transesterification and polycondensation reactions.

Melting. Dimethyl terephthalate (DMT) is melted at 150 – 160 °C in a stirred tank heated with steam, carrier oil, or electricity in an inert atmosphere (nitrogen).

Transesterification. The molten DMT and ethylene glycol are reacted in heated, stirred transesterification reactors at 150 – 200 °C. At the start of the reaction (at normal pressure in a nitrogen atmosphere) the lower temperature range is preferred to minimize sublimation of DMT. The methanol released during the transesterification is continuously distilled off from the reaction mixture. The excess of ethylene glycol is normally ca. 0.5 – 1 mol/mol DMT.

The use of catalysts is essential to achieve a reasonable transesterification rate at moderate temperatures. Although the catalysts listed in the patent literature cover practically the whole periodic system, weakly basic compounds such as amines, metal oxides, alkoxides, and acetates are used as transesterification catalysts in practice at a concentration of 0.01 – 0.1 wt % referred to DMT. Systematic investigations showed that the rate constant for the transesterification of DMT with ethylene glycol correlates with the electronegativity of the catalyst metal ion [52]. Metal compounds in which the electronegativity of the metal ion is in the range 1 – 1.7 are most effective (e.g., acetates of Ca, Mg, Zn, Cd, Pb, and Co). An almost identical order is found when the stability constants of the metal dibenzoylmethane complexes are related to the rate constants of the transesterification reaction [53].

The choice of a suitable catalyst is an important factor in the production of PETP as regards the economy of the production process and quality of the end product. Transesterification should proceed as quantitatively as possible because residual methyl ester groups can interfere with subsequent polycondensation [54]. This is particularly true if the activity of the transesterification catalysts is lowered by additives introduced at the polycondensation stage. The course of transesterification is therefore controlled by the amount of methanol released, whereby entrained ethylene glycol has to be taken into account (density measurement or ultrasonic monitoring).

Polycondensation. The transesterification product is added as a melt to the polycondensation reactor, which can be heated to over 300 °C and must be equipped with a very efficient stirrer. Some of the excess ethylene glycol is often first distilled off at normal pressure (protective gas, nitrogen) by gradually increasing the temperature to ca. 250 °C. Polycondensation then follows, with a reduction in pressure and a further increase in temperature. In order to obtain sufficiently high molecular masses, temperatures of ca. 270 – 280 °C at a final vacuum of <1 mbar are required.

Like the transesterification reaction, the polycondensation reaction has to be accelerated by catalysts. All the catalysts used for transesterification are, in principle, also suitable for polycondensation because the two reactions are extremely similar. The catalyst remaining in the reaction mixture after the transesterification can therefore be used further for polycondensation. This approach does not always provide satisfactory products, however, because active transesterification catalysts decrease the thermal stability of PETP [55]. In many cases the transesterification catalyst is therefore masked with suitable additives (mainly phosphorus compounds) and replaced by special polycondensation catalysts, usually antimony, germanium, titanium, or lead compounds at a concentration of 0.005 – 0.05 wt % referred to DMT.

Rapid polycondensation is achieved by quickly removing the eleminated ethylene glycol by means of intensive mixing and a maximum polymer melt surface area. In conventional

polycondensation plants this is achieved by intensive stirring. Distribution of the polymer melt in thin-film procedures as in thin-layer evaporators or in annular disk reactors is, however, more effective for obtaining very high molecular masses.

Polycondensation is stopped when a defined melt viscosity (measure of the molecular mass), is reached. The power consumption of the stirrer motor is often an adequate indicator of melt viscosity. In order to terminate polycondensation, the vacuum in the reaction vessel is removed with oxygen-free nitrogen and the melt is expelled from the reactor either under nitrogen pressure or, preferably, with spinning pumps. The melt is directly quenched with water and comminuted into chips or pellets to prevent oxidation by atmospheric oxygen.

Conventional batchwise and continuous polycondensation produces PETP that is processed into threads and fibers (solution viscosity ca. 50 – 80 cm^3/g measured in phenol/tetrachloroethane 60/40 wt % at a concentration of 0.0023 g/cm^3, see Section 3.3).

Before further processing the PETP must be carefully dried at 80 – 130 °C to reduce the water content to below 0.01 wt %. Drying is performed with the same apparatus used for solid-phase postcondensation. Heating during drying causes crystallization of PETP which is necessary to avoid agglomeration of the particles during prolonged storage.

A PETP with a fairly high intrinsic viscosity, such as can be produced with the thin-layer evaporator or annular disk reactor, is required for the plastics sector. Alternatively, however, the comminuted PETP (chips, pellets, etc.) is often subjected to solid-phase postcondensation for a fairly long time (~20 h) at temperatures of up to 250 °C in an inert gas stream or in vacuo, resulting in an increase in molecular mass. The rate-determining step in this reaction is diffusion of the eliminated ethylene glycol from the polymer particles, which depends on the particle size [56]. Postcondensation in the solid phase can be performed either batchwise (in vacuum dryers or in a fluidized bed) or continuously (in countercurrent with hot nitrogen).

Production Example for PETP [57]. 12.8 kg of DMT and 8.1 kg of ethylene glycol are transesterified in the presence of 3.32 g of manganese acetate and 0.83 g of cobalt acetate for 3 h at 195 °C under nitrogen in a 30-L steel reactor equipped with an anchor-type stirrer and a distillation column. The liberated methanol is distilled off. 10.76 g of triphenyl phosphate is then added and stirred in for 30 min at 195 °C; 2.75 g of germanium oxide and 0.5 g of tetraisopropyl titanate are added and stirring is continued for a further 30 min.

The temperature of the reaction mixture is then raised to 280 °C within 6 h and the pressure subsequently reduced to 0.3 mbar in 2 h. After a further 2 h under these conditions the vacuum is removed with nitrogen. The polyester melt is extruded in the form of strands, which are cooled in water and then pelletized. The solution viscosity of the polyester is 62 cm^3/g (in phenol/tetrachloroethane 60/40, concentration 0.0023 g/cm^3).

3.2.3. Production of Poly(Ethylene Terephthalate) from Terephthalic Acid

The direct esterification of terephthalic acid (TA) with ethylene glycol became important when economic processes were developed for producing fiber-grade TA [58]. An important advance was made when the reaction times were reduced by performing esterification under pressure (2.7 – 5.5 bar) at temperatures above the boiling point of ethylene glycol (198 °C) [59], [60].

The TA process now yields products that are qualitatively competitive with the polyesters produced in the DMT process (see Table 1) [61].

Table 1. Quality specifications for additive-free PETP used for film production [61]

Specification	Raw material	
	DMT	TA
Intrinsic viscosity, cm^3/g	65 ± 0.015	65 ± 0.015
Carboxyl terminal groups, mmol/kg	20 – 30	20 – 30
Ash content, wt %	<0.04	<0.02
Diethylene glycol content, wt %	0.5 – 1.2	0.7 – 1.2
Filter value (15 µm filter braid), bar cm^2/kg	<30	<30

In new plants direct esterification is the preferred method of PETP production. The advantages of direct esterification with TA compared with transesterification with DMT are

1) The higher reaction rate
2) The lower weight of TA compared with DMT (storage costs)
3) The use of water instead of methanol as condensation agent
4) No transesterification catalyst is required
5) Higher molecular masses are obtained

Temperatures of around 220 – 260 °C are generally maintained to overcome the sparing solubility of TA. The water formed is continuously removed by distillation. The molar ratio of ethylene glycol to TA should be < 2 (in most patents < 1.5 is specified) to suppress formation of diethylene glycol (see page 10). Direct esterification is possible without catalysts, but can be accelerated by basic catalysts (amines) or transesterification catalysts (usually Sb_2O_3).

Esterification is followed by gradual pressure release, the temperature is simultaneously increased and excess ethylene glycol is distilled off. The formation of PETP takes place in the polycondensation stage, which proceeds analogously to the DMT – ethylene glycol process as regards temperature, pressure, and catalysts (see Section 3.2.2, a detailed process description is given in [62], [63]).

Direct esterification at normal pressure can be achieved in a PETP precondensate as reaction medium, in which TA is readily soluble [64]. This process is particularly suitable for continuous direct esterification.

The secondary reactions occurring during polycondensation are of decisive importance in determining the quality of the PETP (see page 10). Ether formation results in diethylene glycol units which have adverse effects on dyeing behavior but also lower thermal and UV stability (for the mechanism of diethylene glycol formation, see [65]). Free carboxylic groups formed by ester pyrolysis have a negative influence on the postcondensation and hydrolysis stability of PETP. Ester pyrolysis also produces olefinic decomposition products that lead to discoloration of PETP.

3.2.4. Production of Poly(Butylene Terephthalate)

Poly(butylene terephthalate) (PBT) is produced analogously to PETP. The currently preferred process is still the transesterification of DMT with 1,4-butanediol followed by polycondensation. The main byproduct is tetrahydrofuran, formed from 1,4-butanediol by dehydration (see page 10). Although some alkyl tin compounds lower tetrahydrofuran formation, the resulting polymers have a lower thermal stability [66]. Although tetrahydrofuran formation is catalyzed by acids, TA is increasingly used as a raw material instead of DMT [67], [68]. For the advantages of the TA method, see Section 3.2.3.

Transesterification of DMT is performed with a slight excess of 1,4-butanediol (molar ratio 1,4-butanediol: DMT < 2, preferably 1.3 – 1.7) at 160 – 220 °C and normal or excess pressure. Soluble titanium compounds are generally used as transesterification catalysts.

Polycondensation at ≤ 260 °C and < 1 mbar is usually also catalyzed by soluble titanium compounds (generally tetraalkyl titanates).

PBT can generally be subjected to polycondensation in the melt to give products with higher molecular masses than PETP (solution viscosity up to ca. 120 cm^3/g, measured in phenol – tetrachloroethane, weight ratio 3 : 2 at 25 °C, concentration 0.0023 g/cm^3). The product is dried in the same way as PETP, see Section 3.2.2. For some uses in the plastics sector (optical waveguide coverings, coatings for bowden wire, headlight dimmers) a higher molecular mass PBT is required, which can also be obtained by solid-phase condensation.

Production Example for PBT [69]. 8.0 kg of DMT and 5.9 kg of 1,4-butanediol (molar ratio with respect to DMT 1.6) are added to a 30-L reactor equipped with an anchor-type stirrer. After heating the mixture to 150 °C, 160 g of a 7 % solution of titanium tetrabutylate in 1,4-butanediol is added over 100 min while stirring to initiate transesterification. After gradual heating to 200 °C over 1.5 h, transesterification is continued for a further 3.5 h at 200 °C, and the methanol formed is distilled off.

The pressure is reduced from 1 bar to 1.3 mbar over 2 h, and the temperature is subsequently increased from 200 to 245 °C in 1 h.

Continued heating at 245 °C and 1.3 mbar for ca. 5 h gives a polymer with an intrinsic viscosity of 124 cm^3/g.

3.2.5. Production of Other Partially Aromatic Polyesters

Other high molecular mass thermoplastic polyesters, such as poly(1,4-cyclohexylenedimethylene terephthalate) [*25135-20-0*], PDCT, copolyesters or copolyetheresters (see → Fibers, 4. Synthetic Organic, Chap. 2.4.2.) are produced in a similar way to PETP and PBT. The different melting points of the end products and different reactivities of the monomers must, however, be taken into account. Depending on their chemical constitution (diol, diester, and diacid), the co-components (see Section 3.4) are added before, during, or after the transesterification phase, or before or during the esterification phase.

Production examples for polyesters based on 1,4-cyclohexanedimethanol [1,4-bis(hydroxymethyl)cyclohexane] and for polyetheresters are given in [70–72].

3.2.6. Production of Fully Aromatic, Liquid Crystalline Polyesters

Fully aromatic, liquid crystalline polyesters can be produced in the melt by three main processes. Direct esterification of phenols with aromatic carboxylic acids in the presence of catalysts such as titanium tetrabutyrate or dibutyl tin diacetate is described in [73]. On account of the high reaction temperatures (>300 °C) there is however the danger of decarboxylation of the carboxylic acids, and the method is therefore restricted to monomers that are stable at the melting point.

A second process involves reacting phenyl esters of aromatic carboxylic acids with relevant phenols. The phenyl esters can be produced by direct esterification or by reaction of diphenyl carbonate with dicarboxylic acids, with the formation of carbon dioxide and phenol.

The commercially available liquid crystalline polyesters Vectra [*81843-52-9*] and Xydar [*31072-56-7*] are produced by a third method: acidolysis of phenolic acetates with aromatic carboxylic acids [74], [75] (see top of the next page).

Vectra

Vectra is synthesized from 4-hydroxybenzoic acid and 6-hydroxy-2-naphthoic acid. Xydar is prepared from 4-hydroxybenzoic acid, 4,4′-dihydroxy-1,1′-biphenyl, and terephthalic acid. The basic structural formulae shown below can be modified by using other monomers such as isophthalic acid or 4-aminobenzoic acid, or by using a different monomer ratio [75–78]. In order to acetylate the phenolic hydroxyl groups, the monomers are added to a stainless steel stirred tank, followed by an excess of acetic anhydride under an inert gas atmosphere (nitrogen). Too large an excess of acetic anhydride affects the color of the polymer and leads to the formation of mixed anhydride structures. Most patents specify a molar ratio of acetic anhydride to phenolic OH groups of 1.02 – 1.18.

The acetylation reaction is performed at 120 – 150 °C under reflux and is complete after 1 to 5 h. The acetic acid that is formed and any acetic anhydride still present are distilled off. The temperature is then raised in stages to ca. 320 °C and a low molecular mass prepolymer is formed. Polycondensation is then usually carried out by gradual reduction of the pressure (<15 mbar) and distilling off further acetic acid until the desired molecular mass (10 000 – 30 000) is obtained. In contrast to Vectra, the maximum molecular mass of Xydar (*mp* 421 °C) in the melt is limited by the higher melting point and higher melt viscosity. Consequently, the Xydar prepolymer, which is still liquid at 320 °C, is discharged from the reactor under an inert gas, granulated, and postcondensed in the solid phase (inert gas or vacuum) at a maximum temperature of 365 °C.

Vectra is synthesized exclusively from high-purity hyroxycarboxylic acids and can, in theory, undergo polycondensation to yield products of infinitely high molecular mass. The molecular mass can be limited by adding small amounts of 4,4′-diacetoxybiphenyl [79]. Catalysts may, however, be added to accelerate acetylation and polycondensation (ca. 25 – 500 ppm referred to the polymer). Catalysts include alkali-metal acetates (e.g., sodium or potassium acetate) and

Xydar

acids (e.g., *p*-toluenesulfonic acid or 2-naphthalenesulfonic acid). Iron ions have a high catalytic activity in the production of Vectra [74]. The iron content of the polymer should not, however, exceed 50 ppm because this has an adverse effect on its thermal properties (see above).

Xydar is often synthesized in the presence of potassium sulfate (25 – 50 ppm referred to the polymer) to improve processibility and appearance of the polymer [75].

Production Example for Vectra [74]. 24.05 kg of 6-hydroxy-2-naphthoic acid and 47.85 kg of 4-hydroxybenzoic acid are added to a 151.4-L steel reactor (stainless steel 316) equipped with a helical stirrer, a solids and liquid trap, and a distillation column. The reactor is alternately evacuated (ca. 9 mbar) and flushed with nitrogen three times. 49.90 kg of acetic anhydride (technical quality) is then added. The reaction mixture is heated to 120 – 140 °C and kept at this temperature for 1 h. The temperature is then raised to 200 °C in 1.5 h. Polycondensation takes place at 200 –327 °C over a period of 3 h under nitrogen (2.8 m^3/h), followed by 1.25 h (at 327 °C) in vacuo (ca. 13 mbar). The hot polymer melt is then extruded and comminuted. The intrinsic viscosity of the polymer in pentafluorophenol at 60 °C (concentration 0.1 wt %) is 540 cm^3/g.

3.3. Analysis

Thermoplastic polyesters have to be analyzed before they are processed. The most important parameter to be determined is the molecular mass because this influences the processability of the molding compounds and the mechanical properties of the article produced from the polyester.

In most cases the molecular mass is determined indirectly via the reduced or specific viscosity (in cm^3/g) in a capillary viscometer (→ Plastics, Analysis). The intrinsic viscosity $[\eta]$ is thus obtained by extrapolation of the reduced viscosity to zero concentration and from this the molecular mass M [80] according to

$$[\eta] = K M^{a}$$

For polymers with a range of molecular masses, M becomes M_n (number average), M_w (weight average), or M_v (viscosity average) depending on the method of determination. See also, → Plastics, General Survey, Chap. 2.2.2.

The reduced viscosity depends on the solvent, concentration, and temperature. For quality control it is normally sufficient to specify the solution viscosity under defined conditions.

The constants K and a have been determined for PETP and PBT under various conditions (see Table 2). For PBT a correlation between the reduced viscosity and M_w is also described [86].

The melt viscosity η_m is just as important a quantity as the solution viscosity as regards the processing of thermoplastic polyesters. Measurement under defined conditions (temperature, viscometer, shear rate, etc.) is sufficient for monitoring quality. Like the solution viscosity, the melt viscosity is related to the molecular mass [87]:

$$\eta_{m,0} = K \bar{M}_w^{3.5}$$

where $\eta_{m,0}$ is the melt viscosity in Pa · s at a shear rate of 0. Values for K in Pa · s are

PETP [88]: $1.13 \times 10^{-14} \exp(-11.9755 + 6082.1/T)$

PBT [85]: 1.02×10^{-14} at 250 °C

Investigations on the melt viscosity of polyetheresters and fully aromatic, liquid crystalline polyesters are described in [89].

The molecular mass distribution of thermoplastic polyesters is determined only in special cases (for methods see [90]), for example to establish the influence of process or reactor technology on the polyesters. Most linear polyesters exhibit a Schulz – Flory distribution (see page 9). Further information on the quality of thermoplastic polyesters is obtained by measuring

Table 2. Constants K and α for PETP and PBT

Polyester	Solvent	K	α	Method of determination	Reference
PETP	phenol – tetrachloroethane 1 : 1, 20 °C	0.0755	0.685	terminal group determination (M_n)	[81]
PETP	2-chlorophenol, 25 °C	0.030	0.74	terminal group determination (M_n)	[82]
PETP	2-chlorophenol, 25 °C	0.0425	0.69	sedimentation, diffusion (M_w)	[82]
PETP	phenol-1,2-dichlorobenzene 1 : 1, 25 °C	0.0469	0.68	light scattering (M_w)	[83]
PETP	phenol – tetrachloroethane 3 : 2, 25 °C	0.0468	0.68	light scattering (M_w)	[84]
PBT	phenol – tetrachloroethane 3 : 2, 30 °C	0.0116	0.87	terminal group determination (M_n)	[85]
PBT	phenol-1,2-dichlorobenzene 1 : 1, 25 °C	0.0437	0.72	light scattering (M_w)	[83]

the melting point, glass transition temperature (both preferably by differential thermal analysis), the hydroxyl terminal groups [91], acid terminal groups [92], and the diglycol content [93].

The water content [94] is also of great importance for the processing of thermoplastic polyesters because water often causes hydrolytic decomposition at high processing temperatures. The equilibrium water content, for a given degree of polymerization $\bar{P}_n$ must not be exceeded on account of the danger of hydrolytic decomposition. This content can be calculated for high conversions from the approximate formula

$$\bar{P}_n = \sqrt{\frac{K}{n_{H_2O}}}$$

$\bar{P}$ where K is the equilibrium constant and n_{H_2O} denotes the number of moles of water per mole of monomer. For example, the maximum water content for PETP ($K \approx 4$) with a molecular mass $M_n \approx 10\,000$ ($\bar{P}_n = 100$) is 0.01 wt %.

A further criterion for the use of thermoplastic polyesters in the fiber or plastics sector is the intrinsic color. This is usually specified as a blue – yellow value (measured with an electric remission photometer) [95].

3.4. Co-Components and Additives [96]

Thermoplastic Copolyesters. The dyeability, elasticity, pilling behavior, shrinkage, hydrophilicity, and flame resistance of polyester fibers can be improved by condensation with appropriate comonomers [97].

The crystallinity, melting point, glass transition temperature, elasticity, flammability, solubility, and other properties of thermoplastic polyesters used in the plastics sector can be modified by selective co-condensation.

Examples of such copolyesters are glass-clear (amorphous) copolyesters based on 1,4-cyclohexanedimethanol, terephthalic acid, and isophthalic acid (i.e., poly(1,4-cyclohexylenedimethylene terephthalate-co-isophthalate) [*26124-27-6*] [98]); elastic copolyesters based on 1,4-butanediol, poly(tetrahydrofurandiol), and terephthalic acid (i.e., poly(butylene terephthalate-co[multibutylenoxy] terephthalate) [71], [72]; neopentyl-glycol-containing copolyesters with good solution properties in paint solvents [99]; and copolyesters based on 1,4-butanediol, terephthalic acid, and isophthalic acid with relatively low melting points for hotmelt adhesives [100]. Thermoplastic copolyesters with elevated glass transition temperatures (and thus im-proved heat resistance) can be obtained by incorporating heterocyclic diols during condensation [101]. For the production of copolyesters, see 3.2.5.

Additives. Raw polymers are seldom processed as such into semifinished or finished articles. Additives are usually added to the polymers in a process known as compounding or formulation. Compounding processes (e.g., mixing, kneading, extrusion, pelletization) are of great importance because the properties, processing, and use of thermoplastic polymers are substantially determined by the additives (e.g., nucleating agents, fillers, flame retardants, stabilizers, pigments).

Nucleating Agents [102], [103]. See also → Plastics, Additives, Chap. 9.1. The processibility of PETP in injection molding is mainly determined by its slow crystallization rate and by the associated danger of cold crystallization (tendency to distortion). High molding temperatures (ca. 140 °C) and addition of nucleating agents are therefore necessary to accelerate the nucleation rate. Inorganic substances such as

talc, magnesium oxide, or clay are added as nucleating agents in concentrations of 0.001 – 1 % with a maximum particle size of 2 – 3 µm. Organic compounds include salts of aromatic carboxylic acids, fatty acid salts, Montan waxes, and polymers such as polyethylene. The nucleating agents can be added at any stage during PETP production or as a powder to the granulate.

PBT and PBT copolyesters with polytetrahydrofuran generally crystallize so rapidly that nucleation is not necessary.

Glass Fibers [104]. See also → Plastics, Additives, Chap. 7. The heat resistance, rigidity, and hardness of thermoplastic polyesters can be considerably increased by adding glass fibers or beads. For example, the heat distortion temperature (according to Martens, DIN 53 458) of PBT reinforced with glass fiber varies as follows:

Heat distortion temperature, °C	50	75	120	160	190
Glass fiber content, wt %	0	10	20	30	50

The glass reinforcement may be added as beads, ground glass fiber, staple glass fiber, or long glass fiber. Maximum heat resistance, rigidity, and hardness are achieved by adding long glass fibers. These additives are mixed with the thermoplastic polyesters in special extruders in a separate compounding stage; amounts of up to 50 % are commonly employed.

Flame Retardants. See also → Flame Retardants, and → Plastics, Additives, Chap. 6. Thermoplastic polyesters (PETP and PBT) have a relatively low flammability because they escape the action of the flame due to melting and droplet formation (oxygen index of PBT, 23 %; UL 94 rating, HB); see also → Flame Retardants, Chap. 3.). Fillers and, in particular, glass fiber reinforcement prevent droplet formation, resulting in a sharp increase in flammability (oxygen index of PBT reinforced with 10 % glass fiber, 19 %). Legislation is increasingly promoting the use of self-extinguishing, nondrip plastics formulations.

Self-extinguishing thermoplastic polyesters are obtained by incorporating ca. 30 % of flame retardants, which are usually aromatic halogenated compounds combinedwith antimony oxide [105] or with phosphorus compounds [106] (see also → Flame Retardants). Examples are brominated polycarbonates [107] and polystyrenes [108], or ethylene(tetrabromophthalimide) in combination with antimony oxide. A combination of red phosphorus and antimony oxide is also used, particularly with PETP [109].

The flame retardants are not normally added during the production of thermoplastic polyesters, but in a subsequent compounding stage.

The polybrominated diphenyl ethers are suspected of producing polybrominated dibenzodioxins and dibenzofurans in the event of fire [110]; they are therefore no longer used in Germany, and interest in halogen-free flame retardants has greatly increased. Up to now, however, only developments and improvements of conventional systems, such as microencapsulated red phosphorus, ammonium polyphosphates, magnesium hydroxide, and magnesium carbonate have been described [111], [112]. The magnesium compounds have the disadvantage that they have to be added in substantially higher amounts and may therefore seriously affect the polymer properties.

Fully aromatic liquid crystalline polyesters have a low flammability and do not require flame retardants.

Stabilizers. See also → Plastics, Additives, Chap. 2., → Plastics, Additives, Chap. 3. In contrast to PETP and PBT, thermoplastic polyetheresters are extremely sensitive to photooxidative decomposition [113] and must be stabilized. Stabilizers include sterically hindered phenols or amines, which are added to the starting substances in an amount of 0.1 –0.5 wt % or are incorporated in the polymer melt [114].

The antioxidant 4,4′-bis(α,α'-dimethylbenzyl)diphenylamine has been approved by the FDA for use in phthalate, isophthalate, and terephthalate polyesters with 1,4-butanediol and polytetrahydrofuran.

Pigments [115], [116]. Pigments with an adequate heat resistance (e.g., titanium dioxide, carbon black, phthalocyanines, quinacridones, cadmium yellow) are suitable for coloring thermoplastic polyesters.

Admixture of Other Polymers. The properties of partially aromatic thermoplastic polyesters can be selectively improved by blending with other polymers. See also, → Polymer Blends, Chap. 4.7. PBTs whose impact properties have been improved with polybutadiene graft rubbers are used in car bumper systems

[117]. Impact strength can also be increased by adding polyethylene [118]. Higher flexibility is obtained by blending with polyether elastomers [119].

New alloying components such as styrene–maleic anhydride copolymers or acrylonitrile–styrene–acrylate copolymers also expand the application range, particularly of PBT [120]. Polymer blends of bisphenol-A-polycarbonate with PBT or PETP have good low-temperature strength and low shrinkage values, they have been commercially successful for several years [121].

Blends with polyurethanes and polyamides [122] or poly-ε-caprolactone [123] are also described.

3.5. Properties

The properties of thermoplastic polyesters depend primarily on the starting compounds (dicarboxylic acids, diols), their molecular mass, and added fillers. The properties of PETP, PBT, and PDCT as fiber raw materials are described in → Fibers, 4. Synthetic Organic, Chap. 2.2.1.,→ Fibers, 4. Synthetic Organic, Chap. 2.4.

PETP and PBT. The two most important thermoplastic polyesters for the plastics sector, namely PETP and PBT, can be described as partially crystalline polymers. They have a high hardness and rigidity, good creep strength, high dimensional stability, and very good slip and wear behavior [124], [125]. Whereas PBT occurs almost exclusively in the partially crystalline form, PETP can also be processed into amorphous molded bodies with high transparency; on heating to 70–100 °C this transparency is lost due to postcrystallization. Transparency can, however, be retained if the polyester chains are forcibly oriented, for example by biaxial stretching and heat setting (transparent films of PETP, → Films, Chap. 6.8.).

A special property of PETP is its slow crystallization, which necessitates molding temperatures of ca. 140 °C and the use of a nucleating agent and crystallization accelerator (see page 16).

PBT and PETP are resistant to water, weak acids and bases, alcohols, ketones, ethers, aliphatic hydrocarbons, and chlorinated aliphatic hydrocarbons at room temperature.

Solvents for PBT and PETP include hexafluoro-2-propanol, hexafluoroacetone, and 2-chlorophenol (mixed solvents, see Table 2).

Hydrolysis proceeds rapidly in the melt in the presence of moisture. The dependence of the hydrolysis rate on temperature and moisture content has been investigated [126], [127].

The most important mechanical, thermal, and electrical properties of PETP and PBT are summarized in Table 3.

Polyetheresters [128–130]. Thermoplastic polyetheresters are block copolymers synthesized from mutually incompatible rigid crystalline and soft amorphous segments. The rigid segments generally consist of an aromatic polyester (e.g., PBT), whereas the soft segments consist of an aliphatic polyether [e.g., poly(butylene glycol) or poly(ethylene glycol)]. On account of the physical cross-linking of the rigid and soft domains, polyetheresters behave like elastomers at the service temperature ($>T_g$, $<mp$). The cross-linking sites are, however, thermally labile and the polymers can therefore be thermoplastically processed above the melting point.

Important thermal, mechanical, and electrical properties of polyetheresters are summarized in Table 4.

The very low glass transition temperature of the polyether (ca. −50 °C) and the high melting point of the polyester (ca. 200 °C) result in polymers with a very broad service temperature range. Polyetheresters with Shore-D hardnesses of 35–72 can be formulated by varying the block length and the ratio of the rigid and soft components.

The special properties depend on the nature of the rigid and soft segments. Copolyesters based on butylene glycol terephthalate crystallize very rapidly from the melt, in contrast to polymers synthesized from ethylene glycol terephthalate blocks. Copolymers with poly-(propylene oxide glycol) and poly(tetramethylene ether glycol) exhibit similar swelling behaviors in water and oil. On the other hand, polymers based on hydrophilic poly(ethylene oxide glycol) swell markedly in hot water, but less in oil. The incorporation of poly(propylene oxide glycol) decreases the thermal stability.

∗ Upper values refer to grades reinforced with long fibers.

Polyetheresters have a good notched bar impact value at low temperature, high strength, flexibility, and abrasion resistance. On account of their partially crystalline nature they are insoluble in most solvents, exceptions include *m*-cresol and tetrachloroethane which are used as solvents for viscosity measurements. The swelling resistance in oils, aliphatic and aromatic hydrocarbons, alcohols, ketones, and esters improves with increasing hardness. Polyetheresters are extremely impermeable to fuels. Their good hydrolysis resistance can be improved by adding polycarbodiimides [135].

The resistance of polyetheresters to light, heat, and oxidation is lower than that of PBT or PETP (for stabilization, see page 17).

Liquid Crystalline Polyesters [136–138]. The two partially crystalline polyesters Xydar and Vectra have only been on the market since the mid 1980s. These liquid crystalline polymers (LCPs) represent one of the most interesting developments in the technical plastics sector. See also → Liquid Crystals, Chap. 4.; → Plastics, General Survey, Chap. 5.3.

On account of their rod-shaped molecular structure, the polymer chains are partially or-

dered in the melt. The macromolecules adopt a parallel orientation in microscopically small regions, with the result that the melt exhibits properties of both a solid (order) and a liquid (mobility). This intermediate state is termed liquid crystalline. Xydar and Vectra have nematic phases, i.e., the longitudinal axes of the molecules are parallel, but the molecular centers of gravity are irregularly distributed (→ Liquid Crystals, Chap. 3.1.). Under the influence of a shear force, such as occurs in normal thermoplastic distribution, the microscopically ordered regions can be macroscopically oriented. This orientation is retained in the solid state and is responsible for the outstanding properties of liquid crystalline polyesters. These properties are, however, strongly orientation-dependent due to the anisotropy of the polymers. LCPs cannot therefore be compared with conventional thermoplastic polymers solely on the basis of values measured on uniaxial test bodies. Nevertheless, LCPs differ from "conventional" thermoplastics as regards the following properties (see also Table 4):

1) Their coefficient of thermal expansion is unusually low for polymers and can reach the values of steel; it can be adapted to other

materials by varying the processing conditions2) Good processibility: on account of their very low melt viscosity, even filigree structural parts can easily be filled
2) Low melt enthalpy (short cycle times)
3) Low flammability: V-0 rating according to UL 94 with wall thickness <0.8 mm
4) High heat resistance
5) Resistance over a wide temperature range to solvents, fuels, and most chemicals, except oxidizing acid and strong alkali
6) Resistant to radiation and transparent to short-wavelength light
7) Low water absorption
8) Very good mechanical properties (strength, impact resistance, modulus of elasticity)

The anisotropy of the mechanical properties and the thermal coefficient of expansion can be reduced by adding fillers (glass fibers, minerals), which simultaneously improve surface quality. LCPs have a poor weld strength, in unfilled LCPs it is about half the strength transverse to the flow direction. To overcome this, special molded parts are constructed in which the weld is located in such a way that it is not subsequently exposed to high stress.

The most important mechanical, thermal, and electrical properties of LCPs are summarized in Table 4.

3.6. Uses

Poly(Ethylene Terephthalate). More than 85 % of PETP is processed into fibers (→ Fibers, 4. Synthetic Organic, Chap. 2.3.3., → Fibers, 4. Synthetic Organic, Chap. 2.3.4., → Fibers, 4. Synthetic Organic, Chap. 2.3.5.). Poly-(1,4-dimethylenecyclohexane terephthalate) is used for special fibers (see → Fibers, 4. Synthetic Organic, Chap. 2.4.2.). The production of high-grade, heat-resistant PETP films is described in → Films, Chap. 6.8. A large proportion of PETP is used to produce gastight bottles for carbonated beverages (see Section 3.8). Highly stressed technical molded parts such as bearings, gearteeth, cam wheels, connectors, bolts, screws, and washers are produced from PETP by injection molding [139].

On account of the processing difficulties (see Section 3.4) fewer molded parts are made from PETP than from PBT. If new developments aimed at reducing the high molding temperatures prove to be successful, this proportion may rapidly increase [140]. Injection molding machines are mainly used for processing.

Trade names include Arnite, Akzo; Crastin, CibaGeigy; Grilpet, EMS-Chemie; Impet, Hoechst Celanese; Melinite, ICI; Rynite, Du Pont; Techster, Rhône-Poulenc; Valox, GE Plastics.

Poly(Butylene Terephthalate). PBT too can be spun into fibers (see → Fibers, 4. Synthetic Organic, Chap. 2.4.), which can be colored, without carriers, with disperse dyes and used in the carpets sector [141]. Trade names are sometimes the same as for PETP fibers. Examples include Trevira, Hoechst; Tergal, Rhône-Poulenc; Fortrell, Celanese.

Most PBT is processed by injection molding and extrusion, a relatively low-viscosity formulation is used for injection molding, and a medium-to high-viscosity formulation for extrusion.

Examples of injection-molded PBT products (unreinforced and reinforced) include housings for heated domestic appliances (e.g., coffee-making machines, egg boilers, toasters, hairdryers); bearing bushes, trip cams, gear wheels, fan wheels, ropesheaves, and pump impellers for the mechanical engineering sector; coil formers, capacitor covers, plug boards, and lamp sockets (often with flame retardants) for the electrical sector.

Protective covering for optical waveguides, films, sheets, monofilaments, and hydraulic lines are produced by extrusion. Paper and board can also be extrusion coated.

Trade names include B. Arnite, Akzo; Celanex, Hoechst Celanese; Crastin, Ciba-Geigy; Grilpet, EMS-Chemie; Orgater, Atochem; PBT, Toray; Pibiter, Montedison; Pocan, Bayer; Rynite, Du Pont; Techster, Rhône-Poulenc; Tenite, Eastman Kodak; Ultradur, BASF; Valox, GE Plastics; Vestodur, Hüls.

Copolyesters. Reference has already been made to possible uses of *thermoplastic copolyesters* (Section 3.4). Copolyetheresters [synthesized from dimethyl terephthalate, 1,4-butanediol, and poly(tetrahydrofuran)diol] are used on account of their high flexibility in the

cold (without plasticizers), particularly for winter sports articles (e.g., ski brakes, soles for cross-country ski shoes, disks for ski poles). A novel field of application is crawlers for snowmobiles, where high abrasion resistance is also required. Copolyetherester elastomers can be processed by rotational casting into tires for vehicles not intended for use on roads (lawnmowers, garden tractors, golf trolleys), and into hydraulic oil tanks. Highly flexible pipes (e.g., for hydraulics lines) can be produced by extrusion.
Trade names include Hytrel, Du Pont; Arnitel, Akzo; Lomod, General Electric Plastics.

Amorphous copolyesters [99] produced from dimethyl terephthalate, terephthalic acid, isophthalic acid, neopentyl glycol, ethylene glycol, and other monomers are soluble in conventional solvents and can be processed into highly elastic, sterilization-resistant coatings (coil coatings). See also → Paints and Coatings, Chap. 2.7.
Trade names include Dynapol L, Hüls; Vitel, Goodyear.

Partly crystalline copolymers based on poly(butylene terephthalate-*co*-isophthalate) are valuable hotmelt adhesives [100] for the shoe industry (shoe soles) or furniture industry.
Trade names include Dynapol S, Hüls; Vestamelt, Hüls.

Copolyesters based on similar starting components are used for powder coatings that produce highly flexible, weather-resistant coatings [142].
Trade names include Dynapol P, Hüls.

Liquid Crystalline Polyesters. Xydar and Vectra types cannot be used without reinforcement or fillers on account of their marked anisotropic properties and tendency to fibrillation. They are usually reinforced or filled with glass fibers, carbon fibers, or minerals and are processed by injection molding.

Areas of application exploit the properties described in Section 3.5. Examples include the automotive and aviation industries, where good thermal and mechanical properties, inherent flame resistance, and low fume formation are important for interior fixtures and fittings.

On account of the low thermal expansion, high heat resistance, and favorable electrical properties, LCPs are employed in the microelectronics and optoelectronics sectors, mainly for integrated circuits, connectors, coil formers, lighting fixtures, and sheathing for glass fiber cables.

On account of their good resistance to chemicals and solvents, LCPs are used as packings in distillation columns and for fuel lines. Vectra (Hoechst-Celanese) and Xydar (Amoco) are transparent to microwave radiation, and are therefore used for microwave cookware and structural parts in microwave ovens.

3.7. Toxicology

High molecular mass polycondensates are usually considered to be biologically inert. However, the biological effect of polymers can be influenced by soluble or volatile components of monomers, oligomers, additives, and degradation products.

The toxicology of PETP has been investigated, especially for its use as a packaging film and textile fiber. No toxic effects were observed [143]. Tests on bacteria showed that neither PETP polyester nor other substances contained in PETP bottles extracted with dichloromethane were mutagenic [144].

PETP, BPT, and various copolyesters with 1,4-cyclohexanedimethanol and/or poly(tetrahydrofurandiol) are permitted by the FDA. They can therefore be used in contact with foods under particular conditions (viscosity, extract content, temperature, etc.) in accordance with CFR from 1988: CFR 170.1240; CFR 177.1315; CFR 177.1590; CFR 177.1630; CFR 177.1660.

Polyterephthalate diol esters are approved by the German health authority (Bundesgesundheitsamt) for use according to the food and commodity law (Aug. 15, 1974). The starting materials which can be used are 1,4-butanediol, ethylene glycol, 1,4-cyclohexanedimethanol, poly(ethylene glycol), terephthalic acid, dimethyl terephthalate, isophthalic acid, adipic acid, azelaic acid, dimethyl azelate, sebacic acid, dimethyl sebacate, *n*-dodecanedioic acid.

3.8. Economic Aspects [140], [145–151]

PETP and PBT. The above-average growth in thermoplastic polyesters that occurred at the start of the 1980s has continued. Double-figure

Table 5. Development of demand for PETP and PBT molding materials (without blends) in 10^3 t

	1984	1986	1988	1989
PETP				
United States	9	13	18	20
Japan	6.5	8	10	12
Western Europe	3.8	5	6	8
PBT				
United States	36	51	60	66
Japan	29	39	49	55
Western Europe	19	23	29	31

growth rates (ca. 15 %) in the PBT and PETP molding materials sector have been achieved worldwide. Table 5 shows the development of demand for PETP and PBT between 1984 and 1989.

Most thermoplastic molding materials are processed in glass-fiber-reinforced form. PETP molding compounds are difficult to process and are therefore used in substantially smaller amounts than PBT molding compounds. The main areas of use are electrical engineering and electronics (25 – 30 % of overall production) and automobile construction (20 – 25 % without blends).

PBT – PETP blends, which have a good surface quality, as well as PBT – polycarbonate blends with high impact strength have become important. The amount of PBT used for blends in 1988 was ca. 10 000 t/a in Western Europe and ca. 20 000 t/a in the United States. The amount of PETP used for blends in 1988 was ca. 2000 t/a in Western Europe and 10 000 t/a in the United States.

PBT is largely used for construction materials, whereas PETP is mainly processed into fibers, sheets, films, and beverage containers. In 1989 15.6×10^6 t of synthetic fibers were produced worldwide; polyester fibers, primarily PETP, accounted for 8.4×10^6 t (54 %). The development of consumption for PETP sheets, films, and bottles is given in Table 6.

Films and sheets of PETP are chiefly used in the photographic sector, magnetic tapes, and packaging materials.

Polyetheresters. The worldwide demand for polyetheresters based on dimethyl terephthalate, 1,4-butanediol, and polytetrahydrofuran was estimated to be 38 000 t in 1991. Of this figure, the United States accounts for 22 000 t and Western Europe and Japan 8000 t each. The annual growth rates are 10 – 15 %. The most important areas of use are hoses, cables, and automobile parts.

Liquid Crystalline Polyesters. The plant capacities for LCPs are ca. 9000 t/a, of which Vectra (Hoechst-Celanese) accounts for ca. 2300 –3600 t/a [152] and Xydar (Amoco) for ca. 4500 t/a [153]. The demand in the United States (ca. 90 % of overall demand), Western Europe, and Japan is considerably lower, at ca. 2500 t/a. However, high average growth rates, particularly in the electrical engineering and electronics sector, of at least 15 % to more than 20 % per annum are anticipated [154].

The major proportion (ca. 60 %) of LCPs is used for electrical and electronics components as well as for microwave-transparent cook ware. The remainder is used in the industrial, telecommunications, automotive, and aviation sectors.

3.9. Recycling

Polyesters (PETP, PBT) play an important role in the production of beverage bottles, foils, films, and fibers. The local authorities, in particular, protest against the increase in the volume of waste caused by the use of nonreturnable polyester bottles. In countries in which these bottles have already been introduced (e.g., USA, Japan, France, Italy, and the UK) laws have been passed to enforce the return and reutilization of the bottles. Because of this, the recycling rate for PETP bottles in the United States, for example, is 90 % [155]. In Europe the proportion of collected PETP is ca. 4 %. Two methods are used for recycling polyester: (1) direct reuse after comminution and washing, and (2) alcoholysis.

Table 6. Development of consumption for PETP sheets/films and bottles in 10^3 t

Region	1984	1986	1988	1989
United States				
Sheets/films	209	200	232	237
Bottles	243	291	334	360
Western Europe				
Sheets/films	130	170	190	195
Bottles	70	110	175	195
Japan				
Sheets/films	93		180	
Bottles	27		65	

It is more difficult to directly reuse PETP foils and films of which the majority consist of composite materials. Such waste can only be processed by combustion or chemical recycling via pyrolysis.

Reuse. Prerequisites for good recycling of PETP materials are [156]:

1) There must be a sufficient amount of homogeneous recyclable material
2) An economical recycling process must be available for cleaning and separating the materials
3) The recovered plastic must have a sufficiently large market and a sufficiently high price to warrant economical recycling

This means that in designing and manufacturing a product, allowances have to be made for its subsequent recycling product. As a result of its high density (1.32 – 1.40 g/cm^3), PETP can be efficiently separated from most other plastics. Separation from poly(vinyl chloride) (PVC) is possible with the help of flotation. High standards are required during sorting for reuse as material for bottles. Due to the incompatability of PETP with the majority of other plastics the proportion of the latter should not exceed 100 ppm, i.e., only one polyethylene or PVC bottle should be among 10 000 PETP bottles.

In addition to collection, the following costs are estimated:

Sorting	0.15 €/kg
Grinding	0.10 €/kg
Washing, drying	0.20 €/kg

In the United States a new plant has been built by Du Pont and Waste Management of North America (WMNA) in Chicago (capacity 20 000 t/a); it separates the PETP chips and converts them to clean polymer. Du Pont then uses or sells the final product [155].

In every recycling step some cyclic and linear oligomers are formed. Especially the linear oligomers cause some problems during processing.

Hydrolysis and Alcoholysis. Another way to break down polyester is hydrolysis or alcoholysis which sometimes requires drastic reaction conditions and long reaction times. The hydrolysis of polyesters results in the formation of carboxylic acids and alcohols, from which new polyester can only be produced after separation and purification.

The breakdown of polyesters is more readily achieved by alcoholysis. The diols and dicarboxylates are formed according to the following reaction scheme:

$$\sim\!\sim R'-CO-O-R-O-CO-R'-CO-O-R\sim\!\sim \xrightarrow{R'OH}$$

$$\sim\!\sim R'COOR' + HOROH + R'OOC-R'-COOR' + HOR\sim\!\sim$$

If methanol is used for the alcoholysis of PETP, the monomers used for its polymerization are reformed. If multifunctional alcohols are employed, polyols can be produced, which can be modified and used for various purposes (e.g., for the production of polyurethane foam). Both processes are carried out on a commercial scale in the United States [157].

Glycolysis to monomer (dihydroxyethyl terephthalate)and low molecular mass oligomers represents a compromise between the regeneration of the starting materials by methanolysis or hydrolysis and direct remelt extrusion. Glycolysis signifies degradation with glycols [158]; it is less expensive than methanolysis or hydro-

lysis and more versatile than remelt extrusion. The resultant low-viscosity monomer can easily be filtered and is repolymerized to a useful molecular mass; it is used as a comonomer and ingredient for controlling luster, color, etc.

Glycolytic recycling can be a batch or continuous process, the rate depending on temperature, catalyst, state of subdivision of the feedstock and the glycolytic PETP ratio. In addition, the final monomer composition is controlled by the reaction time and holdup time after depolymerization. Low ratios of glycol to ester permit higher temperatures and faster reactions but result in higher molecular mass oligomers. Side reactions occurring during depolymerization are minimized by the addition of a buffer such as sodium acetate and by limiting the storage time at high temperature. PETP scrap suitable for glycolytic recycling includes production waste, fibers, films, flakes, and bottles; however, ingredients leading to side reactions, copolymers, end caps, or color must be minimized for critical products and satisfactory repolymerization rates.

Pyrolysis. If the polyester waste is highly soiled or combined with other materials, then in most cases it can only be chemically recycled by pyrolysis [159]. Pyrolysis denotes thermal decomposition under the exclusion of air. Mixtures of hydrocarbons are obtained, whose value is smaller than that of the glycolysis products but higher than that of the pure calorific value.

In the process developed by the University of Hamburg, polyester and other plastics are broken down in a fluidized bed that is indirectly heated by radial thermal pipes [160]. The fluidized bed consists of fine-grained sand (0.3 – 0.5 mm) and is heated to 650 – 850 °C. The pulverized polyester waste is transferred into the fluidized bed with a screw. After leaving the reactor the pyrolysis products are freed of entrained sand and fillers in a cyclone and cooled, whereby oils are condensed and expelled. The residual gas serves for the fluidization of the bed and as heating gas for the burner and other purposes. The plant has a capacity of 20 – 50 kg/h.

120.5 kg of chips consisting of PETP or exposed photographic films were fed with a screw (capacity 18.9 kg/h) into the fluidized bed and heated to 768 or 700 °C, respectively [161]. Table 7 summarizes the product groups obtained from PETP. The fraction of water, which is low (2.1 wt %), is the result of adhering moisture and formation during the decomposition of PETP. There are more water and solid residues in the pyrolysis products of film materials (Table 8). The main gaseous components are carbon monoxide and dioxide. Of the hydrocarbons, only methane and ethylene have notable percentages. The net calorific value (13.4 MJ/m^3) is ca. 40 % of the value for natural gas. As a result of its hydrogen content of 8.7 vol % the gas burns with a less vigorous flame.

Table 7. Products obtained after pyrolysis of 120.5 kg polyester at 768 °C in a fluidized bed

Products	Content	
	kg	wt %
Gas	61.2	50.8

Tar ($bp > 340$ °C)	8.7	7.2
Soot (organic solids)	8.6	7.1
Water	2.5	2.1

Table 8. Components (wt %) obtained after pyrolysis of PETP at 768 °C and film material (PETP, polyethylene, and gelatin) at 700 °C

Component	Pure PETP	Used film
Hydrogen	0.30	0.37
Methane	3.80	5.28
Ethane	0.24	1.70
Ethylene	1.50	3.44
Propene	0.08	1.73
Butene	0.01	0.41
Butadiene	0.04	0.27
Carbon dioxide	17.20	17.30
Carbon monoxide	24.70	16.39
Benzene	18.30	7.79
Toluene	2.50	1.48
Styrene, ethylbenzene	2.55	6.26
Indene	0.41	0.23
Naphthalene	1.40	2.04
Biphenyl	1.47	0.97
Fluorene	0.18	0.10
Ketones, acetates	0.15	0.12
Acetophenone	1.40	1.81
Other compounds	11.87	11.15
Carbon black, fillers	7.10	13.40
Water	2.10	8.76

The largest oil fraction is the benzene- and toluene-boiling fraction, in which the benzene, toluene, and xylene (BTX) aromatics account for over 97 %. This means that pyrolysis of 1 t of polyester waste yields 215 kg of the petrochemically valuable BTX aromatics. The concentra-

tions of the aliphatic and heteroatom-containing hydrocarbons are both < 0.2 wt %. These low concentrations make the processing of this pyrolysis oil fraction to BTX aromatics very much easier.

In contrast, the high-boiling components, constitute a multicomponent system. This fraction, including tars, accounts for 17.8 wt %. The main components are naphthalene, biphenyl, indene, and acetophenone. The high content of acetophenone (10 wt %) is characteristic of the pyrolysis of polyester (PETP). This compound is not formed during the pyrolysis of polyolefins. After pyrolysis the remainder of the oxygen bound to the polyester is distributed as follows: 62 % in carbon dioxide, 31.6 % in carbon monoxide, 5.5 % in water, 0.75 % in acetophenone, and 0.15 % in other keto-compounds and carboxylic acids.

The pyrolysis of polyester and composite materials such as films (PETP, polyethylene, gelatin) in the fluidized bed showed that oxygen-containing plastics can be largely defunctionalized and high proportions of mononuclear aromatics can be obtained.

Polyether Rubber → Rubber, 3. Synthetic
Polyetherimides → Polymers, High-Temperature
Polyethers → Polyoxyalkylenes
Polyethers → Polyoxymethylenes
Polyethers → Poly(Phenylene Oxides)
Polyethylene → Polyolefins
Poly(Ethylene Glycols) → Polyoxyalkylenes
Polyethyleneimine → Aziridine
Poly(Ethylene Oxide) → Polyoxyalkylenes
Poly(Ethylene Terephthalate) → Polyesters
Polyformaldehyde → Polyoxymethylenes
Polyhydroxybenzenes → Phenol Derivatives

Polyimides

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated in Plastics, Properties and Testing. Fundamental aspects of polymerization reactions are treated in Polymerization Processes

1. Introduction

The field of thermally stable heteroaromatic polymers is dominated by the polyimides. After several decades of research and development, the polyimides stand virtually alone as useful heat-resistant materials. They have been used as adhesives, fibers (→ High-Performance Fibers, Chap. 3.2.3.2.), films (→ Films, Chap. 6.11.), foams (→ Foamed Plastics, Chap. 4.9.), plastic moldings, resin matrices for composites, and wire-coating enamels. More recently their use as resin matrices has attracted the greatest attention [1] and synthetic activity.

The polyimides discussed in Chapters 2, 3 and 4 are synthesized from aromatic/heterocyclic monomers and can be loosely classified as condensation (Section 2.1), thermoplastic (Section 2.2), or addition (Section 2.3) types. Table 1 summarizes the trade names of these polyimides, their chemical structure, and classification. Strictly speaking, only those polyimides formed by addition reactions are thermosetting. The condensation type often behave in a similar way, when fully imidized many of them are almost completely insoluble and infusible.

Polymethacrylimides and their derivatives represent a special group of polyimides in which the imidization occurs after polymerization of unsaturated acyclic monomers. They are discussed in Chapter 5.

In 1988 the market for all types of polyimide was: United States ca. 4000 t, Japan ca. 850 t, and Western Europe ca. 800 t. All three markets were expected to grow annually by 10 – 20 % at least up to 1993.

The needs of the defense industry and the high-temperature requirements of the electronics industry have promoted the use of polyimide coatings, films, and laminates. Nevertheless molding resins dominate the market, amounting to 28 % of the total demand in Western Europe. Films are the next largest sector except in the United States where wire enamels take precedence. The films are used primarily in flexible printed circuit boards and for magnet wire insulation. Laminates are also used mainly in multilayer printed circuit boards.

2. Production

2.1. Condensation Polyimides

Most practical routes to polyimides up to the early 1970s involved condensation reactions [2]. Synthesis comprises low-temperature (ca. 50 °C) polycondensation of an aromatic dianhydride with a diamine in a polar solvent, (e.g., dimethylacetamide) to yield a soluble, fusible intermediate, i.e., polyamic acid [3–7]. Fibers, films, or impregnated fibrous reinforcements are

produced from this intermediate which is then converted to the fully cyclized polyimide, either by the action of heat (200 – 300 °C) [8–10], or chemically [11–14] using, for example, carboxylic acid anhydrides in the presence of tertiary amine catalysts as dehydrating agents (Fig. 1).

To obtain polyamic acid with a high molecular mass (necessary for films and fibers), strict attention must be paid to the purity, stoichiometry, and order of mixing of the reactants [8], [15]. High molecular mass is not a prerequisite for adhesives or for resin matrices for composites; here the main problems lie in the hydrolytic instability of the polyamic acid [8–10] and the volatile compounds (e.g., water, methanol, acetic acid) evolved during the cyclodehydration curing process which make processing more difficult. (The two stages of the reaction are covered in detail in [16]). The instability of the intermediate polyamic acids means that they must be stored

under rigorously dry, refrigerated conditions and even then shelf-life is strictly limited (several months). Water is evolved during imidization at elevated temperature leading to yet more hydrolysis. An additional difficulty, especially with the fabrication of thick samples, is that both softening and flow of the polyamic acid and cyclization to polyimide occur over similar temperature ranges. This necessitates careful control of processing conditions and frequently long, complex cure cycles.

Some of these problems have been alleviated by modifying the synthetic route illustrated in Figure 1. For example, use of semiesters of the anhydrides [17] or diacetylated diamines [18] means that an alcohol or acetic acid is eliminated during imidization rather than water (see figure on the left).

The intermediate polyamic acid formed from the diacetylated diamine is hydrolytically stable. The processing window between flow and cyclization is also increased. An additional advantage is that low-boiling, relatively nonpolar solvents (e.g., acetone) may be used for synthesis.

Volatiles are still produced during cyclization and this problem can only be overcome by synthesizing thermoplastic polyimides or variants which are cured by addition rather than condensation reactions.

2.2. Thermoplastic Polyimides

Thermoplastic polyimides are obtained by introducing large cyclic side groups into the polymer chain, by "tailoring" random sequences into the chain, or by the interposition of flexible, aliphatic linking groups between the aromatic and heterocyclic moieties. Russian workers have pursued the first approach and have produced "cardo" or "loop" polymers [19–21]:

X = O, CO, NH

The solubility and fusibility of these polymers are governed both by the nature of the cyclic side group and the imide portion of the chain. If softening points (glass transition temperatures) are to remain below ca. 360 °C, then aliphatic units must also be introduced into the chain. One general drawback of thermoplastic polymers is that for use at elevated temperatures their softening points (glass transition temperatures) must be high (> 200 °C) and hence their processing temperatures must be even higher. This can be overcome by using intramolecular cyclization of active pendant groups which react at relatively low temperatures and increase the proportion of in-chain fused rings, thus raising the maximum use temperature [22], [23] (see top of right column).

Increased processibility may also be achieved by "tailoring" a random sequence into the polymer chain, the resultant dissymmetry accentuating the amorphous as opposed to the crystalline nature of the material [24], [25]:

$T_g \approx 220$ °C

240–250 °C

$T_g \approx 360$ °C

A similar effect has been achieved by using 5[6]-amino-1(4-aminophenyl)-1,3,3-trimethylindane [26] or 3,3′-diaminobenzophenone [27] as the diamine component:

5[6]-Amino-1-(4-aminophenyl)-1,3,3-trimethylindane

3,3′-Diaminobenzophenone

The incorporation of aliphatic linking groups normally lowers thermo-oxidative stability. An exception is the use of perfluoroalkylene groups [28], [29]:

Ultem [*61128-24-3*]

Depending upon the values of x and y, polymers can be made with softening points from 150 °C upwards [30], [31]. They have been used as metal-to-metal adhesives and as laminating resins.

The most successful linking groups from the commercial point of view have been amide, ester, and ether. Amideimides have been prepared from precursors containing a preformed imide ring [32], but the most common route involves reaction of trimellitic anhydride with aromatic diamines or diisocyanates [33], [34]:

Esterimides, on the other hand, are normally made by reacting trimellitic anhydride with a diol, followed by reaction with a diamine [35]:

A polyetherimide (Ultem) was first marketed in 1982 and is produced by a nitro displacement polymerization process [36–39]. See → Polymers, High-Temperature, Chap. 2. (See figure on top of this page)

Although the amide, ester, and ether groups convey superior processing properties, they result in substantially lower thermal stability than that of the conventional aromatic – heterocyclic condensation polyimides. Considerable interest has therefore been centered on the addition polyimides where the aim is to achieve easier production whilst retaining heat resistance (Section 2.3).

2.3. Addition Polyimides

Addition polyimides usually consist of short-chain preimidized oligomers with reactive end groups that can react by addition polymerization. The end groups used have been norbornene (endomethylenetetrahydrophthalimide), maleimide, acetylenic (ethynyl), allylnadic, and benzocyclobutene.

2.3.1. Norbornene End Groups

The first example of this type of polyimide to become commerically available was based upon a low molecular mass (ca. 1300) amic acid prepolymer endcapped with reactive norbornene rings [40–43]:

A solution of this prepolymer is used to impregnate fibrous reinforcement, the solvent (normally dimethylformamide) removed, and the polymer imidized by gradually heating from 65 to 204 °C:

This polymer melts and flows above 260 °C and subsequently cross-links by "pyrolytic polymerization" of the unsaturated end groups at ca. 300 °C. Formerly this had been accepted to be a reverse Diels – Alder reaction with cyclopentadiene being released from the norbornene ring followed by its almost simultaneous polymerization with the maleimide ring also formed.

From a study of model compound reactions for the polymerization of monomeric reactants in situ (PMR) process an alternative mechanism has been suggested.

A variety of dianhydrides (Ar) and diamines (R) have been used to form the central unit of the chain, but the preferred reactants are mainly the same as those employed in condensation polyimides [44]. Although there is no elimination of volatiles due to imidization, considerable processing problems still arise from the high melt viscosity of the polymer, its short reaction time (which necessitates high heat buildup rates), and the difficulty of removing residual polar solvent. These difficulties have been overcome to a large extent by the PMR process. The norbornene chemistry involved is similar to that outlined above, but the semiesters of the anhydrides are normally used instead of the anhydrides and the impregnating solutions contain only monomeric reagents. All polymerization occurs in situ (e.g., on fibers). The principle of the PMR-15 system, which has received practical application, is shown in Figure 2 [45–48].

Other variants include the PMR-11 [49], [50], LARC-13 [51], and LARC-160 (Langley Research Center) [52] systems.

The PMR-15 system is most widely used as a resin matrix for composites. In common with many other high-temperature thermosets, it suffers from microcracking on thermal cycling. This tendency has been reduced by lowering the normal cure temperature (315 – 340 °C) to 280 – 290 °C [53]. In addition to lowering the thermal stresses induced in the material, a modified polymer network of reduced rigidity is also produced. The reactions occurring during thermal imidization of PMR-15 are very complex leading to prepolymers containing imide, amide, ester, anhydride, and salt functionalities [54]. Wide variations in prepolymer molecular mass and molecular mass distribution are also observed. The polymerization of *N*-phenylnadimide has been studied as a model for the cross-linking of PMR-15 [55].

Figure 1. Synthesis of polyimides

2.3.2. Maleimide End Groups

The second type of addition polyimide is based on the bismaleimide structure, where cure oc-

Figure 2. The principle of the PMR-15 system [45–48]

curs by a combination of addition reactions and Michael's reaction with amines [56–58]:

Use of a stoichiometric mixture of bismaleimide and diamine without an initiator results solely in linear chain extension and a polymer whose properties deteriorate rapidly at elevated temperatures. Free-radical cure, however, gives a very tightly cross-linked, brittle material. To obtain an optimum combination of properties, a careful balance must be maintained between the two reactions. This is achieved by using a judicious mixture of initiators and inhibitors [59]. Care must also be taken in the choice of solvent because the thermal stability of the product is very dependent upon residual solvent traces [60].

To obtain better processibility, toughness, and resistance to hot wet conditions than in bismaleimide homopolymers, attention has been devoted to blends of bismaleimides, either with themselves or with other comonomers. For example, the mixture of the three bismaleimides shown below forms a low melting point eutectic, which is specially adapted for filament winding applications [61]:

Other variants include blends of amide-linked maleimides and bismaleimides [62]:

A number of comonomers have been developed as "curing agents" for bismaleimides.

Bis(propenylphenoxy)benzophenone is claimed to increase flexural strength and fracture toughness and to decrease moisture absorption [63]:

Cross-linking occurs between the maleimide and propenylphenyl groups.

Significant improvement in toughness is also achieved by the use of allylphenyl comonomers [64]. Benzocyclobutene-terminated imides can also be copolymerized with bismaleimides yielding other structures (see Section 2.3.5).

A drawback of introducing alicyclic structures into the polymer is that the thermal stability is reduced compared with a fully aromatic – heterocyclic structure. Use of acetylenic termination (Section 2.3.3) was initially hoped to overcome this.

2.3.3. Acetylenic End Groups

Relatively large imide prepolymers were synthesized with acetylenic end groups, which reacted thermally at 220 – 250 °C [65], [66].

The hope was that the end groups would trimerize to yield phenylene rings and hence preserve heat resistance.

A complex mixture of products was obtained, however, which included a polyene structure containing 5 – 6 conjugated unsaturated bonds [67]. This has an adverse effect on thermo-oxidative stability. An acetylenic-terminated isoimide has also been synthesized [68]. The isoimide structure conveys better flow and solubility characteristics, but at elevated temperatures it rearranges to the imide.

Acetylenic-terminated polyimides have been synthesized from combinations of aromatic dianhydrides, aromatic diamines, and aromatic end-capping units [69], [70]. Polymers based upon 4,4′-(hexafluoroisopropylidene)bisphthalic anhydride are most attractive from the processing point of view since they are soluble in common solvents (e.g., acetone, tetrahydrofuran) [71].

2.3.4. Allylnadic End Groups

A series of allylnadic imides, ranging from low-viscosity liquids to low-melting solids have been synthesized using dicyclopentadiene as starting material [72]. The dicyclopentadiene is thermally cracked and the resulting monocyclopentadiene is transformed to the desired products by a variety of routes.

These materials can be cured thermally and the cure can be accelerated by cationic additives (e.g., latent sulfonic acid). The cure mechanism probably involves a combination of cyclopolymerization and Diels – Alder rearrangements. The products have glass transition temperatures in excess of 300 °C.

2.3.5. Benzocyclobutene End Groups

Benzocyclobutene-terminated imides are easily synthesized by reaction of 4-aminobenzocyclobutene and aromatic tetracarboxylic acid dianhydrides:

Under appropriate thermal conditions the strained four-membered ring of the benzocyclobutene opens to yield an extremely reactive diene, bis(*o*-quinodimethane), which then dimerizes:

Another possible reaction is 1,4-addition analogous to the polymerization of *o*-xylylene [73], [74]:

A benzocyclobutene-terminated imide can also be copolymerized with a conventional bismaleimide via a Diels – Alder reaction between the maleimide and *o*-quinodimethane groups [75]:

Little data on these systems are available to date.

3. Processing

Adhesives. Condensation, thermoplastic, and addition polyimides and polyamideimides have all been evaluated as metal-to-metal adhesives [76]. In the case of the condensation polymers, a solution of the intermediate polyamic acid is applied to a glass cloth carrier, and the bulk of the solvent removed by heating to 100 – 150 °C. The partially cured material is then placed between the adherends and cure is completed under pressure at high temperature (e.g., 0.5 MPa at 316 °C for 90 min). A postcure of some hours at 300 – 350 °C is necessary for optimum properties [77].

Fibers. See also, → High-Performance Fibers, Chap. 3.2.3.2. Fibers have been produced by wet spinning of thermoplastic polyimides [78] (e.g., Upjohns 2080 [79] or Upilex [80]). The alternative approach is to form polyamic acid fibers from solutions of prepolymer and to submit these to chemical, thermal, and mechanical treatment to produce the polyimide fibers. Russian authors have been especially active in this field and the main features of the two-step manufacturing process are described in [81]. Conventional wet and dry spinning equipment may be used.

Films. See also, → Films, Chap. 6.11.. The polyimide derived from pyromellitic dianhydride and 4,4′-diaminodiphenyl ether has dominated film production [2]. Films are cast from solutions of the intermediate polyamic acid and then converted to polyimide by heating at 300 °C. Commercial polyimide films are also available which are coated on one or both sides with fluorinated ethylene resin. That provides a

heat-sealable surface and also improves resistance to bases and concentrated acids.

Foams. See also, → Foamed Plastics, Chap. 4.9. Foams have mainly been produced from condensation polyimides. The powder obtained after spray drying the polyamic acid solution is foamed into blocks by heating in a microwave oven. The water and alcohol liberated during imidization act as the blowing agents. Syntactic foams have also been manufactured, for example, by mixing equal weights of polyimide and silica microballoons and processing at 300 °C under moderate pressure.

Plastic Moldings. Processing conditions depend on polyimide type. Some condensation polymers are subjected to powder metallurgy techniques to cold-form a part followed by sintering at 360 – 380 °C [82]. Direct or transfer compression molding at temperatures up to 350 °C and pressures up to 30 MPa has been used for thermoplastic and addition-type polyimides and for polyamideimides. Injection molding is carried out by placing the polymer in either pellet or powder form into the heated cavity (350 °C) of an injection molding machine, allowing softening to occur, and then injecting into a cooled cavity (230 °C), where the part remains until it is below its glass transition temperature. For high-quality moldings, prolonged annealing cycles are recommended, e.g., for a 12-mm thick article: 36 h at 150 °C, 36 h at 177 °C, 36 h at 204 °C, 36 h at 232 °C, and 48 h at 260 °C. Moldings are produced with a variety of fillers (e.g., short carbon or glass fibers, graphite, molybdenum disulfide, polytetrafluoroethylene).

Resin Matrices for Composites [1]. See also, → Composite Materials, Chap. 4.2. The processing of carbon fiber prepreg to produce laminates depends upon the type of polyimide used for impregnation, the equipment (autoclave or press), and the shape of the item and its thickness. Data for press cure of the different types of polyimide are summarized in Table 2. These are taken, wherever possible, from schedules recommended by the resin manufacturers. Some polyimides are not suitable for autoclave curing. The thermoplastic polyimides require the highest press temperatures, but no postcure cycle is necessary. The condensation and addition polyimides are fabricated at lower temperatures and, in general, at lower pressures, but require extended postcure cycles. For the condensation and acetylenic end-capped polymers a complicated stepwise postcure is essential for the development of optimum properties.

Wire-Coating Enamels. Polyesterimides find their major use in this area. Wire-coating formulations based upon polyamideimides and condensation polyimides are also available. The coated wires are produced with conventional equipment. The varnishes are deposited on the surface from solution, dried to remove solvent, and then cured in the case of the condensation polyimide by heating to ≥ 350 °C. For the other materials cure temperatures of ≥ 175 °C are required.

4. Properties and Uses

The properties of the different polyimide types in their diverse applications cannot all be listed here. Since the main justification for their use is their high temperature capability, this aspect of their behavior will be emphasized. Figure 3 compares the thermal stabilities of polyimides on the basis of weight loss [83]. The superior stability of the fully aromatic – heterocyclic polymers (e) compared with the addition polymers containing alicyclic rings (a) and (c) is evident. The relatively low thermo-oxidative stability of the polymer derived from the oligomers with acetylenic end groups (b) is a function of the polyene structure which results from polymerization of these materials [67].

Figure 3. Comparison of thermal stability in air of different types of polyimide
a) Bismaleimide; b) Acetylenic; c) Norbornene; d) Thermoplastic; e) Condensation

Table 2. Comparison of press cure parameters

Polyimide type	Temperature, °C	Pressure, MPa	Time, min	Postcure	
				Temperature, °C	Time, h
Bismaleimide	120 – 180	1.4	60	250	24
Condensation	205	1.7	30, cooling	205 – 345	16
Acetylenic	205	1.4	60 – 120, cooling	230 – 400	22
PMR	232 – 315	6.9	90, cooling	343	16
Norbornene	315	1.4	60	not necessary	
Thermoplastic 2	250 – 350	2.0 – 3.5	60, cooling	none	
Thermoplastic 1	427	17.3	10, cooling	none	

Adhesives. Most commercial polyimide adhesives are supported on glass cloth carriers and contain antioxidants, generally arsenic compounds, to prolong service life at elevated temperatures. Aluminum powder is also often added to reduce thermal stress and to act as a reinforcing agent. Table 3 gives data for lap-shear joints (overlap of two materials bonded with adhe-sives) tested at elevated temperatures and made from condensation, thermoplastic, and addition polymers. The lap-shear strength is a standard test for adhesives and is a measure of the strength required to pull the joint apart. Attempts have been made to toughen the brittle LARC-13 adhesive matrix by the incorporation of elastomers [84]. Fluorosilicone or vinyl-terminated silicone elastomers were physically blended with the LARC-13 amic acid; alternatively, aromatic amine-terminated butadiene – acrylonitrile (ATBN) or silicone (ATS) elastomers were chemically reacted into the prepolymer backbone. The effect of these additions on elevated temperature properties is, however, generally deleterious.

The main applications of these heat-resistant adhesives are in the aerospace and electrical industry.

Fibers. Fibers have been made on a pilot-plant scale in the United States and the former Soviet Union from both condensation and thermoplastic polyimides. Figure 4 illustrates strength retention as a function of time and temperature in wet-spun fibers [79]. Table 4 gives heat aging data on a number of experimental polypyromellitimide fibers [16]. The fibers may be used for heat-resistant insulating materials, filter cloths, flameproof clothing, reinforcement of rubber articles, electrical insulation, and atomic reactors. The last of these uses is possible because of the high stability of polyimides to ionizing radiation.

Figure 4. Strength retention of wet-spun polyimide fibers (Upjohn Polyimide 2080, thermoplastic type) as a function of time at 250 and 300 °C

Films. The first major application of a condensation polyimide was as a film – Du Pont's Kapton has been marketed since 1961. Table 5 gives typical properties of 0.0254-mm (0.001 inch) Kapton H film and also of Kapton H coated on one or both sides with fluorinated ethylene – propene resin. The coating provides heat-sealing capability and improves chemical resistance. Films have also been produced from the thermoplastic polyimide based upon diaminodiphenylindane [85], some mechanical properties at various temperatures are listed in Table 6.

The main area of use of polyimide films is electrical insulation. The aerospace industry employs them for wire, cable, slot, and winding insulation. They have also been specified for electric locomotive motors, subway trains, and motors of immersed petroleum pumps. Other applications include flexible printed circuits, magnetic tapes, and solar sails.

∗ RT=Room temperature.

Foams. Conventional and syntactic foams have both been produced from condensation polyimides. Table 7 gives the compressive strengths at room and elevated temperatures of foams of differing density [86]. Figure 5 compares the temperature dependence of compressive strength of conventional and syntactic polyimide foams [87]. These foams have very low flame spread and smoke production. Their main applications are in acoustic and thermal insulation, e.g., vibration and heat protection for electronic equipment, light-weight fire barriers, and cryogenic insulation for fuel tanks. They have been employed in aircraft and rocket construction.

Plastic Moldings. Tables 8 and 9 list mechanical properties of unfilled and graphite-filled polyimide moldings, respectively, at elevated temperatures. Comparison of results is not simple because the moldings contain various amounts of filler and testing was done at different temperatures. Absolute figures may also depend upon whether testing is done perpendicular or parallel to the direction of molding. The former gives higher values (except for compressive strength) and hence only these are quoted.

The moldings have many applications (e.g., seals, gaskets, piston rings, pressure disks, sleeves, bearings, sliding and guide rods, valve shafts, and gear wheels). They are used in nuclear equipment, jet engines, data processing

Resin Matrices for Composites. This area has seen the marketing of the greatest number and variety of polyimides. A vast amount of data is available, especially on carbon-fiber-reinforced materials. Absolute strength values depend very much on the type of carbon fiber used for reinforcement. Tables 10 and 11 compare carbon fiber – polyimide resin unidirectional laminates based upon percentage retentions of interlaminar shear strength, flexural strength, and flexural modulus with time of aging at different temperatures. Table 10 also includes average figures for the initial room temperature values of these mechanical properties for the polyimides and carbon fiber. The data show that at least 80 % of the initial properties are retained at 200 °C for up to 1500 h. At higher temperatures the lifetimes of composites based upon 50 % retention of flexural strength are 1820 h at 232 °C, 1350 h at 300 °C and 470 h at 316 °C. These figures must be regarded as maximum values because, in service, the effects of absorbed moisture and applied stress must be considered in addition to thermo-oxidative aging.

Figure 5. Compressive strength retention of polyimide foams as a function of temperature
a) Blown foam; b) Syntactic foam

The major application of these composites is as components of primary and secondary structures in the aerospace industry. They are also used in the electrical and electronics industry (e.g., for printed circuit boards).

Wire-Coating Enamels. Insulating coatings for electrical wiring have been made from polyimides (condensation type), polyamideimides, and polyesterimides. The polyimide coating has the best thermal stability with projected lifetimes of 100 000 h (>11 years) at 200 °C, 25 000 h (>2 years) at 240 °C, 10 000 h at 260 °C and 1000 h at 325 °C. Its drawbacks are low abrasion resistance, limited shelf-life of the coating solutions, and cost. The polyamideimides and polyesterimides overcome some of these drawbacks but at the expense of heat resistance. The polyimide coating also exhibits high elasticity at very low temperatures. A 0.625-mm diameter wire can be wrapped around a 3-mm diameter mandrel at 4 K without the coating cracking. With a polyester coating, cracking would occur on wrapping around an 18-mm diameter bar. Figure 6 compares the service lives of polyimide, polyamideimide, and polyester coatings [88].

The main applications of the coatings are in electrical equipment and machines that are operated at elevated temperatures.

5. Polymethacrylimides

Production. Commercial production of polymethacrylimides has been known since 1939 [89] and generally involved the use of

a preformed polymeric resin, usually a methacrylic ester such as poly(methyl methacrylate) [*9011-14-7*], or a polymeric acid such as poly(methacrylic acid) [*79-41-4*], and an ammonia or amine source such as a free amine, ammonium salt, urea, or nitrile. These reactions, usually carried out in unpressurized vessels at about 140 – 210 °C for several hours, gave fairly high imidization levels, but the polymers contained significant amounts of methacrylic acid groups and associated ammoni-um or alkyl ammonium salts. This type of material was generally not suitable for thermoplastic uses because of the

evolution of volatiles (methanol, water, amines) at thermoplastic processing temperatures.

Figure 6. Comparison of service lives of wire-coating enamels
a) Polyesters; b) Polyamideimide; c) Polyimide

A later process [90] using a pressurized autoclave at higher temperatures and pressures for longer times, allowed a satisfactory degree of imidization (> 95 %) in the recovered (insoluble phase) polymer, so that the polymer was better suited for thermoplastic uses.

However, polymethacrylimides found their main commercial use as foamed polymers, using a variation of the above chemistry in which the nitrogen source was copolymerized into the polymer backbone, and pyrolytic cyclization – imidization reactions were carried out (→ Foamed Plastics, Chap. 4.10.) [91–94].

Other early methods for forming polymeric (meth)acrylimides included cyclopolymerization of imide-containing monomers [95–97], and treatment of methacrylic films with ammonia or amine [98], [99].

More recently, a continuous high-pressure reactive extrusion – devolatilization process has been developed [100]. A (meth)acrylate polymer is treated with substantially anhydrous ammonia or amine at high pressure and temperature in an extruder, followed by subatmospheric devolatilization. The advantage of this process is that nearly all cyclization reactions (imide and anhydride formation) are complete within the residence time of the extrusion, and residual volatiles levels are extremely low. This leads to a widely processible thermoplastic, which is suitable for injection or blow molding, thermoforming, etc.

Due to the fairly unusual chemistry that takes place in reactions of amines and polymethacrylates at high temperatures, formation of methacrylic acid, acid salts, and methacrylic anhydride is observed (Fig. 7). This is believed to occur via an unusual alkyl – oxygen cleavage mechanism. The consequent alkylation of amines required by this pathway has been observed [101–103], and a similar mechanism using dialkylamines and polymethacrylates to generate methyl methacrylate/methacrylic anhydride polymers has also been reported [104].

These thermoplastic polymethacrylimides can be improved further by a two-step continuous imidization – re-esterification process [17–19] in which the level of methacrylic acid (**1**) and anhydride (**2**) functionality in the final imide copolymer can be decreased or eliminated. This, in turn, substantially increases processibility, weatherability, flow, and miscibility of the imide copolymer with other polymers. Other imidization process modifications have also been reported [108–130].

Properties and Uses. The imidization of poly(methyl methacrylate) by most of the above processes can be accomplished with ammonia or primary alkyl amines. Imidization with ammonia gives rise to a mixed NH/NCH_3 polyimide functionality due to the incorporation of some of the alkylated amine into the polymer [130]. At high imidization levels (ca. 90 – 100 %), these materials, when prepared by the reactive extrusion process, have high glass transition temperatures (215 – 225 °C), good tensile strength (96 – 110 MPa, ASTM D-638) and modulus (4130 – 5170 MPa), high decomposition temperatures (1 %, thermogravimetric analysis, N_2, 390 – 405 °C), good oxidative stability, chemical resistance, and impact resistance similar to acrylic polymers. When methylamine is used as the imidizing agent, materials with a slightly lower glass transition temperature (ca. 168 – 180 °C at 90 – 100 % imidization) are obtained but the polymer is lower in color, better in weatherability, and more easily processed. A commercial grade of thermoplastic poly(*N*-methyl methacrylimide (KAMAX T-170, Rohm and Haas, USA) of ca. 90 wt % imidization and $\bar{M}_W$ 125 000 has the following properties [131]:

Refractive index	1.54
Density	1.22 g/cm^3
Coefficient of thermal expansion (23 °C)	4.7×10^{-5} K^{-1}
Tensile strength (23 °C)	79 MPa
Flexural strength (23 °C)	138 MPa
Flexural modulus (23 °C)	4270 MPa
Notched Izod impact strength (23 °C)	21 J/M
Heat distortion temperature under flexural load at 1.82 MPa, annealed at 130 °C for 4 h	156 °C
Glass transition temperature	168 °C
Total light transmission/haze (ASTM D 1003-61)	90 %/2 %

Because of their high modulus, tensile strength, heat distortion resistance, and optical properties, poly(*N*-methylmethacrylimides) are finding broad use in glazing and lighting applications. Automotive uses include taillight and headlight covers and bezels, where high hardness, surface gloss, optical transmittance, retroreflectivity, heat resistance, and weatherability are required.

Figure 7. Reaction of poly(methyl methacrylate) with methylamine
∗ Dimethylamine formed in this reaction also participates in formation of methacrylic acid from methyl methacrylate (with generation of trimethylamine).

In siloxane-coated formulations, the high dimensional stability, rigidity, and low weight of these polymers make them useful for large glazing parts such as "targa" tops and "T" top automotive roofing units. High-wattage light piping and light guides are another use, where the superior optical clarity is an advantage over polycarbonate. Instrument clusters are also a growing

area of use. An area under development is high-intensity discharge (HID) lighting applications where very high heat and UV resistance over a long time period are needed.

Other uses of polymethacrylimides include photoresist resins [99], [132], packaging, medical devices, food and cosmetic containers, gas barriers, adhesives, and in polymer blends [133–138].

Polymethacrylimides containing some residual acid and anhydride functionality are useful as reactive compatibilizers and processing aids. In polyamide blends, for instance, polymer grafting reactions occur to give block copolymers [139].

1. Introduction

A continuous need for new materials is created by the increasing complexity of products that result from technological breakthroughs and the desire to obtain improved, cheaper materials for existing applications. Alongside the development of new improved base polymers and their copolymers, blend technology is one of the most widely used routes to satisfy this need. Polymer blends (also known as alloys) are combinations of two polymers with one or more distinctive properties that contribute to or are required for the proper functioning of a specific application. Their enhanced, especially adapted property profiles provide advantages to the processor and end user such as extra ease of processing, better low-temperature impact performance, higher strength, higher or lower gloss, reduced flammability, and higher transparency, often in combination with a lower price.

The first generation of blends was developed in the 1950s to improve impact performance. This impact modification normally requires the utilization of rubbery components (materials with a low glass transition temperature, T_g, and generally based on polybutadiene structures) that need a stabilization package. The first impact-modified grades were either made by special polymerization techniques (e.g., copolymerization, block and graft polymerization) or by compounding techniques. Their properties are based upon those of the main matrix polymer and are consequently limited in their scope of application. Although impact properties were improved, a number of undesirable properties were introduced (e.g., delamination, poor surface quality, and inconsistent property profiles). Better materials were made by introducing core – shell impact modifiers. A polymer with a property profile that fulfills market requirements in all areas does not exist.

Introduced in the early 1960s, engineering polymers such as PC and PPE (Table 1) became available as new basic resins for further blend developments. These second-generation blends offer improved heat resistance and higher con-

tinuous use temperatures compared to the older generation materials.

Table 1. Thermoplastics

Type of plastic	Abbreviation	Name
Commodity	PE	polyethylene
	PP	polypropylene
	PS	polystyrene
	PVC	poly(vinyl chloride)
Transitional	ABS	acrylonitrile – butadiene – styrene copolymer
	SAN	styrene – acrylonitrile copolymer
	SMA copolymer	styrene – maleic anhydride copolymer
		acrylics
Engineering	PA	polyamide
	PBT	poly(butylene terephthalate)
	PC	polycarbonate
	PETP	poly(ethylene terephthalate)
	POM	polyoxymethylene
	PPE	poly(2,6-dimethyl-1,4-phenylene ether)
	SMA terpolymer	styrene – maleic anhydride terpolymer
High-performance	PEI	polyetherimide
	PPS	poly(phenylene sulfide)
	PSU	polysulfone

Thermoplastics can be classified into commodity, transitional, engineering, and high-performance plastics (Table 1). Commodity or bulk plastics are made in large volumes, and generally have a low continuous use temperature. High-performance thermoplastics have a high temperature resistance but a low production volume and high price.

Engineering polymer blends are a special group of plastics, whose applications are related to and depend on their specially designed property profile. They all offer dimensional stability over a wide range of maximum temperatures in combination with a minimum continuous use temperature of 85 °C. In addition, they usually possess high impact resistance over a wide range of temperatures down to as low as − 40 °C. Their dimensional stability is determined by the component with the highest glass transition temperature or by the combination of a high crystallinity and high melting point of the highestmelting component. The latter case can be exploited best by reinforcement with inorganic fillers or fibers. The use of a polymer with a high glass transition temperature as a functional filler yields even more interesting systems because they are not restricted to a limiting volume fraction and orientation of the reinforcement. Figures 1 and 2 compare engineering blends with thermoplastics and composites in terms of continuous use temperatures and impact strengths.

Figure 1. Second-generation polymer blends of engineering plastics

Figure 2. Relationship between mechanical properties and impact strength for various thermoplastic materials

In 1990 blends accounted for 10 % of total thermoplastics production [1–7]. Annual growth figures of 6 – 8 % are predicted versus 2 –3 % for other plastics. Upgrading products based on commodity plastics by reinforcing or blending with engineering polymers creates a very competitive situation for engineering plastics. It has

been estimated that the U.S. market for speciality polymeric blends was $\$900\times10^6$ in 1990, and was growing at an annual rate of 7 % [7]. Growth rates for individual engineering blends depend on:

1) Growth rate of major application area (e.g., automotive appliance) [8]
2) Continent of interest (U.S., Europe, Japan)
3) Position in product life cycle: e.g., PPE – HIPS blends are considered a mature blend compared with PC – ABS, and will therefore experience lower growth figure.

Companies that offer blends usually manufacture one or more of the blend components [9]. More polymer manufacturers and compounders are entering this business now because most basic patents for the production of thermoplastics have expired (e.g., PPE, PC) and blends allow facile expansion of the product range [4], [9–11].

Figure 3. Schematic representation of blend development

From a technical point of view, it is important to translate the demands of a given application to the key physical and mechanical properties of the engineering plastics blends. Target values for heat and chemical resistance, high- and low-temperature impact strength, and stiffness should be assessed. The rationale used for choosing two (or more) polymers (the blend) for a specific application is important (Fig. 3). The dominant factor that determines whether a specific polymer blend is suitable for a certain application is the requirement profile (Chap. 2). The requirement can either be one demanded by the customer or end user, or one imposed by the standards of the specific industry segment (e.g., flammability standards in the aircraft industry).

Two polymers may be miscible, partially miscible, immiscible, or compatible. Consequently, the property profile resulting from blending two polymers is not a simple combination of the two individual property profiles. The relation between different blend classifications in terms of properties and morphology are discussed in Chapter 3. Techniques used to influence blend thermodynamics and ultimate property profile are also considered.

The general guidelines for the identification of a blend property profile are outlined in Chapter 4, and are subsequently applied to the most important blends. Once a blend of two polymers has been selected, qualification of the resin for a certain application depends on processing and design considerations (Chap. 5). Chapter 6 focusses on new developments in polymer blends.

2. Market Requirements

Specification of material requirements is determined by the needs of the end user and by the standards within an industry segment. All materials have to fulfill the requirements specified by industrial standards or mandated by law. These standards are controlled by standardized test methods and vary for different countries and industrial segments.

Blend development starts from the combination of a required property profile and an existing technology. The main industrial application areas for polymer blends are the automotive market, followed by the packaging industry, electronic and electrical industry, business equipment, and appliance sectors. Smaller application segments are construction, consumer goods, sheet manufacturers, and aerospace industries.

Automotive Applications. A number of different application areas can be discerned in an

automible. Horizontal exterior body parts demand a higher temperature resistance than vertical exterior body parts since they absorb more radiation from the sun. Both types require high surface quality and facile paintability, the coating technique being determined by the temperature resistance of the material. Mechanical properties are very important for structural body parts, but nonstructural body parts also require a high dimensional stability as characterized by a low coefficient of thermal expansion.

Bumper, or better bumper systems, have a crash-absorbing and an aesthetic function. The crash-absorbing function of bumper systems can be fulfilled by incorporating appropriate failure mechanisms. Decorative functions demand easy paintability, high UV resistance, and resistance to small impact loads. The trend is towards a separation of both functions. Facile dismantling is becoming important for recycling.

Wheel covers should have a good dimensional stability and be able to withstand the high temperatures caused by braking. Chemical resistance is usually provided by a coating.

Lighting systems consist of a light-reflecting component and a housing. The latter requires an extremely high dimensional stability and related mechanical properties. The reflector must be temperature resistant and possess sufficient reflecting capacity (surface quality and gloss).

The *passenger compartment* contains a high number of decorative applications designed for comfort. Resistance to low continuous loads (e.g., instruments in instrument panel) and glossy/nonglossy appearance are general considerations. The temperature requirement is related to exposure to the sun, but a heat distortion temperature of 120 °C is generally accepted. Key requirements for the dashboard material include a minimum heat distortion temperature of 120 °C, excellent accoustic properties (reduction of outside and engine noise), high impact resistance, and good scratch resistance. Paintability and compatibility with soft-touch overlay films are additional requirements.

Structural parts (e.g., chassis) demand such high mechanical properties that composites are the only feasible solution. *Under-the-hood applications* include cable and wiring, which demand electrical, chemical, and high-temperature resistance.

Fuel tanks place high demands on the barrier properties of the resin, in addition to its chemical resistance. PE in fuel tanks has been subjected to (sulfo)fluorination to increase surface polarity and improve barrier properties. Other techniques are employed in utilizing PA – PE or PA – PVAL and PVAL – PA blends [PVA = poly(vinyl alcohol)] for fuel tanks where a special layered morphology ensures impenetrability.

Applications in the *motor compartment* have to withstand harsh environmental conditions, and thus require a high-temperature and environmental (including chemical) resistance. The most suitable products are semicrystalline polymers.

Electronic and Electrical Applications. The dominating requirements in this industry are high heat and chemical resistance and high dimensional stability. A key requirement is a low, preferably temperature-independent, conductivity. The trend towards miniaturization demands better flowing resins coupled with a high heat resistance. Higher heat materials are also required for the introduction of the surface-mount circuit-board assembly [11] in which thermoplastics are combined with metals. The materials must be able to withstand chemical cleaning baths and temperatures over 260 °C for more than 1 min resulting from high-temperature soldering via wave, vapor-phase, IR, or laser methods. Dimensional stability should be maintained during these operations and under operating conditions. Electrical (office) equipment must fulfill stringent flammability requirements, particularly when used in restricted areas.

Appliance Sector. Basic requirements for household appliances are water resistance, chemical resistance, appearance (glossy etc.), and temperature resistance. Electrical properties (e.g., conductivity) and absence of toxicity risks must conform to consumer and government standards.

Building and Construction Applications. Material requirements differ from country to country. Public buildings are subject to the most severe rulings. The greatest drawback of plastics is their intrinsic flammability resulting from their organic nature. The fire tests mandated for plastics are thus difficult to pass. To reduce the

risk of fire, only relatively small amounts of plastics can be used in low-risk areas (e.g., outside sidings). The most important flammability characteristics are ignition and flame propagation behavior. Materials may have horizontal, vertical, or no fire propagation. Assessment of flammability characteristics is extremely complex, since the behavior of materials under fire conditions depends not only on the nature of the material, but also on its thickness and the configuration of the part.

Mechanical requirements are much easier to fulfill and depend largely upon the temperature resistance of the material.

Packaging Applications and Pipes. Basic requirements for packaging materials are barrier properties for water, oxygen, and carbon dioxide as well as excellent extrudability resulting from a high melt strength. Permeability requirements are usually satisfied by multilayer systems in which polymers are alternated with tie layers. Properties can be optimized by bidirectional orientation. These multilayer systems can be substituted by a single, special two-phase blend material.

Pipes for water distribution should have a long guaranteed life time (>100 years), and prevent migration of low molecular mass compounds into the water.

Figure 4. Possibilities of blend morphology

3. Blend Technologies

From a thermodynamic perspective, polymer blends may be completely miscible, partially miscible, or immiscible (Fig. 4). An almost fluid transition is possible between these systems; by modifying the base polymers each blend can be optimally positioned for the foreseen application.

3.1. Thermodynamics

The thermodynamic blend requirements have been reviewed elsewhere [12–15]. Blend polymers interact with each other in their amorphous state, either in a melt or dissolved in a common solvent. A thermodynamically stable mixture of two polymers is obtained if the free energy of the mixture is lower than the combined values of the individual components, i.e., the energy of mixing ΔG_{mix} should be negative. The free energy of mixing is composed of an enthalpy and entropy term [12–15]

$$\Delta G_{\mathrm{mix}} = \Delta H_{\mathrm{mix}} - T\Delta S_{\mathrm{mix}} \tag{1}$$

A homogeneous blend over the complete composition range of two components 1 and 2 is only obtained if

$$\left(\partial^2 G/\partial x^2\right) > 0 \tag{2}$$

in which x denotes the volume fraction of component 2. The entropy contribution to the overall free energy of the system is usually negligible, and is only important in special cases (e.g., blending with relatively low molecular mass components such as plasticizers).

The enthalpy resulting from the interaction energy between the two polymers determines whether they are completely or partially miscible. Complete mutual solubility results in a single-phase system. Partial solubility provides a two-phase system with a very low interfacial energy allowing the production of very finely dispersed blend systems without the need for a third component such as a compatibilizing block copolymer. Normally, even when very similar components, such as polyolefins are blended, the enthalpy term is positive and leads to nonmiscibility. Phase separation can only be prevented if interaction between the different chemical groups in the two polymers is possible (e.g.,

dipole – dipole interaction, charge transfer complex formation, hydrogen bonding). A negative enthalpy value leads to a completely or partially miscible blend system. The miscibility of a two- component system can be improved by increasing the interaction energy between the two components or reducing the interaction energy within each component. The latter effect is achieved by using random copolymers made from monomers that, by themselves, form immiscible homopolymers. The internal repulsion energy in these copolymers can thus improve miscibility [16]. The interaction energy between two polymers is the main factor that determines the final blend result.

Figure 5. A schematic phase diagram for a polymer – polymer blend with a lower critical solution temperature (LCST)

The morphology of incompletely miscible systems can be structured. In a two-phase system with a dispersed phase and a continuous phase, the polymer constituting the more important continuous phase can be selected. The second possibility consists of an interpenetrating, co- continuous network formed from both polymers (Fig. 4). Morphological control depends on chemical interaction and rheological factors such as the melt viscosity ratio of the two polymers and the dependence of melt viscosity on shear rate. The compounding conditions used during melt blending are therefore of major importance for the final blend property profile (see Section 3.2 and Fig. 3).

The influence of temperature on blend thermodynamics is important because it determines phase separation behavior and morphology (see Section 5.1). A typical example is shown in Figure 5. Three regions can be discerned: (1) a thermodynamically stable region (miscibility), (2) a metastable region where the system is stable only towards small concentration fluctuations, and (3) a region where spinodal decomposition yields a two-phase system. The binodal (solid line) corresponds to $\Delta G_{\mathrm{mix}} = 0$, the spinodal (dashed-dotted line) is defined by $(\partial^2 G/\partial x^2) = 0$.

3.2. Compatibility

The term compatibility describes all useful (scientific) means of producing stable blend microstructures that provide technologically important properties for the performance of the part. In the absence of interactions between two blend components, the blend morphology is largely determined by the interfacial tension. The interface between two polymers in the melt is characterized by the interfacial tension and the domain adhesion [17]. The interfacial tension γ_{12} between polymers 1 and 2 is defined as the work required to increase the interface

$$\gamma_{12} = (\delta G/\delta A)_{P,T,n} \tag{3}$$

where A is the surface area between polymers 1 and 2. The magnitude of the interfacial tension is determined primarily by the polarity difference between the two phases [17]. It is also related to the surface tensions of the constituent polymers which are defined as the work required to increase the surface of a polymer by 1 cm^2. Increase in the surface area of a polymer involves the transport of polymer segments from the bulk to the surface which deprives them of the small forces acting in the bulk (e.g., van der Waals forces). In total,

$$\gamma_{12} = \gamma_1 + \gamma_2 - W_{\mathrm{a}} \tag{4}$$

where γ_1 and γ_2 are the surface tensions of polymers 1 and 2, and W_{a} is the work of adhesion (equal to the decrease in Gibbs free energy on forming an interface between polymers 1 and 2). In practical terms this means that the work

of adhesion increases as the interfacial attraction increases, corresponding to a decrease in interfacial tension. If two immiscible polymers are mixed, more interface is created and the free energy of the system increases. The system is thermodynamically unstable and strives toward a reduction of the total interface surface. Consequently, if two individually dispersed polymer droplets encounter each other, they agglomerate immediately. This leads to coarsening of the phase morphology which can only be prevented by the use of compatibilizers. A compatibilizer reduces the interfacial tension, improves the interfacial adhesion, permits finer dispersion during mixing, and stabilizes morphology during processing.

The most common types of compatibilizers are AB block copolymers for a blend of polymers A and B (Fig. 6) that are added prior to compounding or synthesized in situ [18], [19]. The block copolymer decreases the interfacial tension by dissolution of the copolymer block segments within their respective homopolymer phases, leading to covalent bonds being positioned across the interface. Physical anchoring of both phases contributes to the stability of the resulting morphology and mechanical strength. In commercial blends, 5 – 15 wt % compatibilizer is used.

Figure 6. Ideal configuration of block copolymer at the interface between polymer phases A and B

Several other routes are available for compatibilizing phases in commercial multicomponent polymer blends. Large-scale phase separation can be prevented by promoting cocrystallization, by cross-linking the dispersed phase, or by the formation of interpenetrating networks. Ionic attraction between blend components can also be used to stabilize the phase structure. High stress shearing conditions may be applied to mechanically interlock both phases, but this technique is seldom practised.

3.3. Compounding

For scientific and screening purposes, limited amounts of blends are prepared by combining solutions of the blend components from the same solvent or mutually miscible solvents. Blends of miscible polymers can then be obtained by solvent evaporation or coprecipitation. Care must be taken not to heat a blend beyond a potential LCST temperature in a subsequent melt processing step. In dealing with partially miscible or compatible systems, coprecipitation followed by a melt cycle is usually employed [20], [21].

The main method of blend production is batch or continuous melt blending in kneaders or compounding extruders [20], [21]. The machines used are corotating twin-screw compounders with a mixing section based on the Erdmenger principle, Busch co-kneaders, and Banbury kneaders.

The technology involved in this method of manufacturing polymer blends is determined by the thermodynamics of the blend system (Section 3.1) and by the rheological conditions during melt blending. The final morphology of the blend in the compounding step is of prime importance for its resulting property profile.

Compounding machines are not simple extruders which merely melt and transport the resin [15], [22], [23]. Intensive mixing of the melt is achieved by the dispersive or distributive action of the screw element. Depending on the thermodynamics of the mixture of molten components, a dispersion of component 1 in 2 or 2 in 1 is obtained. The criteria determining the continuous phase are the volume fractions used in the melt-blending process, the ratio of the individual melt viscosities, and the surface tension (the polymer

with the lowest surface tension usually becomes the continuous phase).

Two basic microrheological processes can be discerned in the blending of polymers: distributive and dispersive mixing. Distributive mixing determines the homogeneous distribution of the second phase throughout the matrix, whereas dispersive mixing causes large particles to break up into smaller ones. During actual mixing both processes occur simultaneously.

Distributive Mixing. At the start of the blending process, the droplet size of the second phase is relatively large. Two counteracting stresses are in effect: the deforming shear stress τ and the interfacial stress σ/R. Their ratio is usually called the capillary number Ca.

$$Ca = \tau R/\sigma = \eta_m \dot{\gamma} R/\sigma \tag{5}$$

where

$\dot{\gamma}$ = shear rate (s^{-1})
η_m = viscosity of matrix (Pa · s)
σ = interfacial tension (N/m)
R = radius of particle (m)

Typical shear stresses in polymer melts are in the order of 10^4 N/m^2. The local radius of a dispersed droplet is approximately 10^{-3} m in the early stages of the mixing process, and σ is typically 10^{-2} N/m. An affine deformation is the result.

The total interface is a measure of the effect of distributive mixing and, in the absence of reorientation, is directly proportional to the total shear γ.

$$A = A_0 \gamma \tag{6}$$

where A is the interfacial area and A_0 the initial interfacial area.

If the layers are oriented along the shearing direction, such as in corotating twin-screw extruders, distributive mixing becomes more efficient.

When two polymers dissolve in each other, they do so by diffusion. The time required for complete dissolution is greatly reduced by decreasing the droplet size of the starting dispersion; this is facilitated by minimal surface tension between the two initially molten phases. The distributive mixing action is produced by the shearing and elongating forces that act upon the continuous phase and are transferred to the dispersed phase [15], [22], [23]. Under stagnant conditions, the dispersed phase consists of molten droplets which are deformed into thread-like structures. The length – diameter ratio of these structures depends on the interfacial tension constraints of the dispersed phase, and on the effectiveness of the transfer of the deformation forces from the continuous phase to the dispersed phase. The latter is maximized when the ratio of the apparent melt viscosities of the continuous and dispersed phases is close to one. Equation (7) describes the equilibrium conditions for droplet formation [24], [25]:

$$\eta_1/\eta_2 = \Phi_1/\Phi_2 \tag{7}$$

where η is the melt viscosity and Φ the partial volume.

Figure 7. Droplet deformation
A) Deformation caused by shear flow; B) Deformation caused by elongational flow; C) Actual droplet formation (combination of A and B)

Dispersive Mixing. The dispersed phase deforms affinely with the fluid motion, resulting in elongated droplets. This process continues until the capillary number approaches unity. This limit is reached if the local radii are in the order of 10^{-6} m, resulting in $\sigma/R = 10^4$ N/m^2. The elongated droplets become unstable due to interfacial tension driven Rayleigh distortions, and droplets are formed, which are again subjected to shear stress.

This process of elongating and breaking up repeats itself until the droplet size reaches an equilibrium dimension determined by the above-mentioned factors. These process steps are shown in Figure 7.

Figure 8. Influence of deformation forces on droplet diameter as a function of viscosity ratio η_1/η_2 with η_1 the dispersed and η_2 the matrix viscosity

Figure 8 illustrates the difference between the effect of shear and elongational flow on particle size. For high viscosity ratios ($\eta_1/\eta_2 > 4$), dispersed particles do not break up in shear flow because they rotate around themselves. Elongational flows are irrotational, and dispersive mixing is possible. The final quality of the blend dispersion depends entirely on this process. The interfacial tension has to be very low(< 5 mN/m) to obtain a dispersed phase with dimensions smaller than 1 µm. In cases when the two blended polymers have a higher interfacial tension, compatibilizers are necessary to obtain the necessary dispersion quality. These compatibilizers are generally block copolymers consisting of monomeric units that are (preferably) miscible or at least highly compatible with the two phases of the blend system. During the melt-mixing process, they position themselves at the interface between the two miscible components, and thus overcome the repulsive effects of interfacial tension by forming chemical bonds between the two blocks. In this way, addition of a compatibilizer leads to a decrease in interfacial tension, yielding smaller particle sizes at the same viscosity ratio and shear stresses. It also provides the necessary morphological stability in this thermodynamically unstable system. Furthermore, mechanical properties are optimized if compatibilizer blocks of sufficient molecular mass are entangled in the relevant polymer phase.

The basic blend of two polymers described above can be regarded as the base matrix, which has to be further adjusted to the needs of the application by addition of additives (e.g., impact modifiers). The location of the impact modifier can be predetermined by chemical bonding with the desired phase or by specific surface interfacial effects.

Predicting Morphology. Why does one of the dispersed resin phases encapsulate the other? Under equilibrium conditions such effects are probably due to interfacial energy differences between the blend components. The tendency of a liquid to spontaneously spread across a solid or liquid substrate can be expressed in terms of the surface and interfacial tensions of the components using Harkin's equation

$$\lambda_{ij} = \gamma_j - \gamma_i - \gamma_{ji} \tag{8}$$

where γ_j, γ_i, and γ_{ji} are the surface and interfacial tensions of the solid, liquid, and solid/liquid respectively, and λ_{ij} is defined as the spreading coefficient. Equation (8) can be approximated by

$$\lambda_{12} = \gamma_1 - \gamma_2 - \frac{4\gamma_1^d\gamma_2^d}{\gamma_1^d + \gamma_2^d} - \frac{4\gamma_1^p\gamma_2^p}{\gamma_1^p + \gamma_2^p} \tag{9}$$

where γ^d and γ^p constitute the distributions of the contribution to the surface tension caused by dispersive and dipole interactions, respectively.

Spreading is predicted to occur only for positive values of λ_{12}. Melt blending is usually carried out at elevated temperature, interfacial tensions should therefore be known at processing temperatures but variation in surface tension with temperature is comparable for most polymers (0.06 – 0.08 dyne · cm/ °C).

With three or more different components a number of interfacial tension combinations result. This can create a competitive situation lead-

ing to a number of options. If the spreading coefficient λ_{12} is positive, component 1 will encapsulate component 2 and as such will be dispersed in 3 (Fig. 9) [26]. A three-phase system develops in those cases where none of the possible three-phase combinations has a positive spreading coefficient. All these morphologies are thermodynamically controlled.

Figure 9. Schematic diagram showing spreading behavior of liquid on solid substrate (A) and one polymer phase on another within a third (B)

One of the most severe problems encountered in blends of two immiscible components with an insufficiently low interfacial tension is loss of morphology or dispersion through agglomerization. This leads to uncontrollable thermodynamically driven, phase separation and delamination with total loss of mechanical properties.

3.4. Reactive Compounding

Reactive compounding is used in those cases where the above-mentioned agglomeration problem has to be overcome by creating chemical bonds across the interface [27]. This technique can be applied with a single-phase matrix and a two-phase blend matrix. An example is phase-selective impact modification where the modifier is chemically bonded to one phase component of the blend matrix. This is possible through the use of specially functionalized components containing reactive groups. One component may be functionalized with a group that can react with an existing reactive site in the second component. Alternatively, both components may be functionalized with mutually reactive sites.

The most commonly used chemical reactions are those between carboxylic acids or anhydrides with amines or epoxy groups, and between amino and epoxy groups. Reactive extrusion involves the introduction of these reactive groups into a nonreactive polymer by means of radically induced graft reactions with unsaturated monomers or by replacing available reactive groups with more or different reactive groups.

The term in situ compatilization denotes those cases where a functional group is introduced to establish chemical bonds between the two phases or to generate a compatibilizer in situ. An example of this technology is found in the manufacture of the completely immiscible blend of PPE and PA with the assistance the addition of, for example, maleic anhydride (see Section 4.5, PPE – PA blends).

Figure 10. Generalized modulus – temperature diagram for two polymers and their blend
a) Amorphous polymer with high T_g; b) Crystalline polymer (e.g., polyamide, polyester) with low T_g; c) Blend of a and b

3.5. Mechanical Properties [28]

Nearly all thermoplastics are subjected to mechanical loading during their lifetime. Mechanical properties are therefore often used as the basis for material selection. Engineering

data sheets supplied by the manufacturer contain information on mechanical properties, thermal properties, electrical properties, flammability behavior, and chemical resistance. These properties are measured by standardized test procedures (e.g., ASTM, DIN, ISO), see → Plastics, Properties and Testing. Important mechanical properties for engineering blends are discussed briefly in this section [28].

Characterization of a thermoplastic (blend) usually starts with a curve of tensile modulus (E) plotted against temperature (Fig. 10).

The *glass transition temperature* T_g (1 Hz) is the temperature at which the larger chain segments either gain or lose rotational freedom. Its location shifts with the frequency of the test method, i.e., the performance of a material is difficult to predict based on merely T_g values. Secondary transitions also play an important role in determining impact resistance, especially if the T_g (1 Hz) lies close to the use (or room) temperature.

Impact strength is the ability of a material to withstand impulsive loadings. Tests are performed using notched and unnotched samples. The material fracture mode is important, being either ductile or brittle and depends on temperature (Fig. 11). The location of the ductile – brittle transition is usually reported.

Figure 11. Typical impact behavior as a function of temperature

The *toughness* (ability to absorb mechanical energy without fracture) is measured as the area under standard (tensile) stress – strain curves. For many (engineering) thermoplastics it is usually improved by the incorporation of a low-modulus component (rubber) as a separate phase [29], [30]. When highly dispersed the rubber acts as an effective stress concentrator and initiates both crazing and shear-yielding phenomena in the matrix. Since both these processes can absorb large amounts of energy, impact-modified materials exhibit superior resistance towards crack propagation under impact conditions. The low-modulus phase may be incorporated by grafting, copolymerization, or melt blending. High stress concentration is reached when the ratio of the moduli of the rubber phase and the matrix is high. This value is increased when the rubber particle cavitates under the onset of the three-dimensional stress in the part.

Enhancement of the intrinsic toughness of the blend system increases impact resistance. The most important factor in optimizing the impact performance of a polymer resin is identifying the preferred deformation mechanism of the matrix polymer – crazing or shear band formation – because each mechanism requires a specific type of impact modification. In all cases the predominant deformation mechanism depends not only on the modified matrix system and its morphology, but also on variations in test conditions.

Two important phenomena are usually considered in *long-term behavior : creep* (the increase in strain for a material subjected to a constant load) and *stress relaxation* (reduction of stress induced in a material subjected to constant strain). Both processes provide estimates of the materials long-term dimensional stability and are important in selecting resins and design parameters for a certain application (see Section 5.2).

The *ultimate use temperature* is the maximum allowed temperature at which the material will provide the required dimensional stability under the foreseen conditions. The *continuous use temperature* is related to the oxidative stability or intrinsic stability of the blend system. This is usually determined by the weakest blend component, whereas the ultimate use temperature of the most thermally stable blend component determines the thermal resistance.

The two most commonly employed ultimate use temperatures are the Vicat softening temperature (Vicat A or B) and the heat distortion (deflection) temperature (HDT). Typical HDT values for completely amorphous polymers are 20 °C lower than the T_g values. The Vicat values are somewhere inbetween. For typical semicrys-

talline polymers, large differences are found between the high- and low-load HDT values. The Vicat values are usually close to the low-load HDT values.

3.6. Additives

The role of additives in modifying polymer properties should not be underestimated. See also, → Plastics, Additives.

The distribution of stabilizers between the various blend components (including impact modifiers) is important. Redistribution of stabilizers initially present in the weakest component, may yield surprising effects. For instance the UV resistance of PC – ABS blends is markedly higher than expected for an ABS system due to the presence of UV stabilizers in the continuous PC phase. Redistribution processes can be prevented by using chemically bonded additives.

Oxidation at moderate temperatures (thermal oxidation) and under the influence of UV radiation (photo-oxidation) can lead to cross-linking, lowering of molecular mass, and deterioration of mechanical properties. Unsaturated rubbery polymers, such as those used for impact modification, are particularly sensitive to attack by oxygen and heat. *Heat stabilizers* and *antioxidants* are added to suppress these reactions.

Flame retardants are applied to allow a polymer to conform to flammability requirements. A large variety of compounds (e.g., aluminum trihydrate, organic phosphates, antimony oxide in combination with various halogen compounds) are used for this purpose. They increase the amount of solid (nonvolatile) material by carbonization or cross-linking, and/or interfere in the oxidation processes taking place in the flame (flame poisoning).

Plasticizers are used to reduce the modulus of the resin (i.e., to increase flexibility) over the expected use temperature range. They are also effective as flow-improving additives and modify the continuous phase. They have to be selected on the basis of compatibility parameters. They are sometimes moderate molecular mass polymers with a low T_g, but more commonly oligomers with a molecular mass of 3000 – 1000. The use of polymeric plasticizers versus the traditional organic materials is growing due to environmental concerns (nonvolatile and less migrating) and also due to practical performance reasons.

Release agents used to provide easy mold release are selected according to their volatility and thermal stability in relation to the processing temperatures.

A number of types of *fillers* exist. Mica and lime are used to increase volume and reduce the material price. Other particulate fillers such as graphite, carbon black, and aluminum flakes are used to enhance the material's conductivity for a variety of purposes. Reinforcing fillers (e.g., glass fibers, continuous glass mats, or glass fabrics) are used chiefly to improve mechanical properties such as modulus and strength and increase the heat distortion temperature (Fig. 2).

Transesterification catalysts in blends of two polyesters may catalyze copolymer forming transesterification reactions during (melt) processing.

Catalyst complexing agents are added to prevent these unwanted side reactions. Compatibilizers have been discussed in Section 3.2. The role of *impact modifiers* has been discussed in Section 3.5.

4. Property and Application Profiles of Selected Blends

Thermoplastics are crystalline or amorphous. Crystalline resins (PA, POM, PP, PSU, polyesters) have superior resistance to organic solvents, a low melt viscosity, and are often not transparent. They also exhibit considerable mold shrinkage and warpage. High dimensional stability is only achieved below the glass transition temperature. Above this temperature, reinforcing fillers (e.g., glass fibers) are required to provide the desired dimensional stability and strength; they also enhance the tensile modulus. Furthermore, the crystallization rate and the history determine whether a material acts according to the characteristics described in Table 2.

Blending with engineering polymers is needed to improve their intrinsic property profile and expand their application range [31]. The amorphous polymers (ABS, PC) have excellent dimensional stability up to 20 °C below their T_g; maintain their properties at elevated temperature; and show good impact behavior, high trans-

parency, and low warpage. Amorphous polymers with a very high T_g are very difficult to process and/or very brittle. Also their application area is limited due to lack of chemical resistance. These issues had to be addressed before they were accepted by the market. Semicrystalline engineering polymers frequently exhibit a too slow or too rapid crystallization with a poorly controlled crystalline phase morphology. This causes a processing-dependent property profile, leading to unpredictable impact behavior. Furthermore their mechanical properties vary widely depending whether they are used below or above their glass transition temperature.

Table 2. Property profile of engineering thermoplastics

Resin	Advantages	Disadvantages
ABS	impact strength, processibility, surface appearance	HDT, flammability
ASA	weathering performance, ductility	HDT
HIPS	processibility, impact strength	chemical resistance, HDT
PA	processibility, impact strength if saturated with water, toughness, chemical resistance (crystalline PA)	water adsorption leads to general change in mechanical properties and dimensional stability, HDT
PBT	chemical and solvent resistance	processibility, shrinkage
PC	low-temperature toughness, HDT, constant modulus, high T_g	stress-crack sensitivity, solvent/chemical resistance, impact strength under certain conditions
PETP	chemical and solvent resistance	shrinkage, low-temperature toughness, crystallization speed
POM	tensile strength, modulus	impact strength
PP	chemical resistance, low price, high flammability	HDT, oxidation sensitive, brittle
PPE	HDT, rigidity, flame retardancy, impact strength	processibility, oxidative stability (UV)
PS	processibility	brittleness
PSU	excellent thermal and oxidative stability	expensive, notch sensitive

The advantages and disadvantages of the most important thermoplastics are listed in Table 2. The key to the development of a successful blend is to maintain the strengths of both polymers while removing their disadvantages. The heat distortion temperatures of these polymers and some engineering blends follow:

ABS	80 – 100
PBT	70
PC	135
PEI	170 – 240
PP	70
PPE	200
PS	80
SMA	105
ABS – PC	110
ABS – SMA	95
PA – PPE	170 – 190
PC – ABS	100 – 125
PC – PBT	120 – 140
PC – SMA	115
PEI – PC	170
PPE – HIPS	80 – 175

In the following sections selected commercially important blends and engineering blends are discussed. The treatment of the blends is based upon the main component (defined as being present in an amount of more than 50 wt %), and not the (for mechanical properties very important) continuous phase. Each section is concluded with a short list of applications that may be similar because different blends are targeted for the same application.

4.1. Polyolefins

Polyethylene. Polyethylene [*9002-88-4*] (PE) is classified according to density which is controlled by the attainable degree of crystallization and the density of the amorphous phase [32]. Densities range from 0.8 to 0.95 g/cm^3 and are primarily determined by their underlaying molecular structure which results from the way these polymers are synthesized. See also → Polyolefins, Chap. 1.

High-density PE (HDPE) is produced by comparatively low-pressure polymerization with Ziegler or complex oxide catalysts; density 0.95 g/cm^3, melting temperature 130 – 135 °C.

Low-density PE (LDPE) is traditionally made by a high-pressure route; density 0.92 g/cm^3, melting temperature 115 °C, but lower crystallinity than HDPE due to presence of branching structures.

Linear low-density PE (LLDPE) is comparable in structure and general properties with LDPE but lacks long- chain branching. It is produced by copolymerizing ethylene with butene, hexene, octene, or 4-methylpentene at low pressure.

Very low-density PE (VLDPE) is an extreme version of LLDPE; density may be as low as 0.88 g/cm^3.

Ethylene copolymers are typically polymers of ethylene with polar monomers such as acrylates.

Ultimate rheological properties can be adjusted by blending to suit the processing techniques used. Density can also be adjusted by blending because it simply follows linear additivity of the components used. From a practical point of view the polyolefin systems are completely compatible due to their very low interfacial tension.

Vinyl, acrylic, and even carbon monoxide comonomers are used to modify polyethylene. The possibilities of these modifications are, however, restricted because crystallinity and melt temperature rapidly decrease with comonomer content, resulting in products with a very low modulus of elasticity. Rubbery materials are produced in this way and are frequently used as impact modifiers for blends. Although chemical modification of polymers is preferred (primarily due to cost reasons) some property profiles can only be obtained through blending.

Polyethylenes are widely used as blend components because they improve a number of important properties such as flow, impact resistance, chemical resistance, and environmental stress cracking sensitivity. Cost – price reductions and volume – price improvements are an additional advantage.

One of the most important application areas of PE blends is the packaging industry. They display barrier properties in particular toward oxygen and water vapor, and chemical resistance toward aqueous systems, edible fats, and oils. In blends of polyamides with slightly functionalized PE, the desired blend morphology is best described by the term controlled delamination (i.e., agglomeration of the dispersed PE phase leads to a two-phase layer structure but does not reach an undesirably high level that would cause delamination). This can only be achieved through extrusion shaping [33]. The inherent incompatibility in PE – PA blends is overcome by chemical bond formation between carboxylic or maleic anhydride groups of the modified PE phase and amine end groups of the PA phase. The following types of compatibilizers have been used: maleic-anhydride or chlorine-modified polyolefins [34], ethylene – methacrylic acid copolymers, ionomers (maleic-anhydride-grafted PE), and epoxy compounds. Increasing the degree of PE modification with polar groups improves the adhesion of these intrinsically nonadhering polymers to more polar polymer blend components to give extremely tough materials [33], [35], [36]. Applications include automotive parts (mainly injection-molded compounds), power tools, farm and garden equipment, as well as sport and recreational markets.

PE – isobutene films have improved properties and toughness compared to HDPE films. Typical applications are single-layer extrusion films, and heavy-duty bags. HDPE, LDPE, and LLDPE polymers are blended in different ratios to obtain films in a customer-preferred density. Uses include films for bags.

Polypropylene. Polypropylene (PP) [*9003-07-0*] (→ Polyolefins, Chap. 2.) is used as homopolymers, random copolymers and block copolymers. Polypropylene is one of the most widely used commodity plastics. It has a good chemical resistance, excellent thermal stability, a low price, and high flowability. The polymer has three drawbacks: (1) it is sensitive to oxidation during processing and use, (2) it has a poor resistance to UV-induced degradation, and (3) it is rather brittle even though its glass transition temperature (− 10 °C) is below room temperature.

Thermal oxidation problems have been solved by use of specially developed additive packages. Impact performance can be improved by chemical modification (copolymerization) or blending. Comonomers are mainly ethylene and higher olefins. Cheap rubbers such as EPDM (ethylene – propylene – diene rubber) are frequently used for blending [37]. The miscibility between polyolefins is extremely limited in spite of their great chemical similarity (Fig. 7). However, due to the small interfacial tension the dispersibility is acceptable. Nevertheless, when blends of PP and other polyolefins are being made, they often require a compatibilizing block copolymer to provide the necessary degree of dispersion and to maintain morphological control during processing. The latter is essential for obtaining the desired mechanical properties of the product. Morphological stability can be fur-

ther enhanced by in situ cross-linking of the dispersed phase (dynamic vulcanization) [38]. The main applications of PP and its blends are in bumper systems and dashboards.

Blending with incompatible polymers can be achieved via utilization of a functionalized PP (e.g., by grafting with maleic anhydride). The inherent interfacial tension differences are thus overcome by means of chemical bonds instead of physical adhesion. Blends of PP and PA based on this technique are becoming available [37].

4.2. Poly(Vinyl Chloride)

Poly(vinyl chloride) [*9002-86-2*] (PVC) is the oldest and one of the most important plastics, see → Poly(Vinyl Chloride). Worldwide sales of PVC-based plastics were expected to exceed 13×10^6 t/a in 1991 [39].

PVC has a number of important properties. Its amorphous character and T_g of 75 °C provide an excellent basis for good dimensional stability under load up to 60 °C. Its high polarity gives chemical resistance towards a broad range of solvents and an excellent flame retardancy. However, pure PVC is rather brittle under notched impact conditions and has a limited thermal stability. This last property has successfully been addressed by stabilization techniques. In combination with extensive utilization of blend technology, all conventional processing techniques are now possible for PVC. The abundant presence of strong polar C – Cl bonds make PVC highly suitable for blending. Depending on the concentration of strongly interacting dipoles in the blend components, completely miscible or compatible blends can easily be created. The resulting two-phase morphologies either have a particulate or a controlled delaminated character which controls the final deformation mechanism and its performance in blends of PVC.

Chlorinated polyethylene (CPE) is being used as a blend component to improve the impact and flow behavior of PVC [40]. Compatibilizers are not necessary because the chlorine content can be adjusted to the required compatibility level (35 wt %).

Similar effects are obtained for copolymers of ethylene and vinyl acetate (EVA) and/or ethylene and ethyl acrylate (EEA) [40]. The ester groups interact with the H – C – Cl groups of the PVC and provide the required compatibility if the comonomer content is in the range 30 – 40 wt %. Afterchlorination of PVC yields CPVC which has a higher heat distortion than PVC. The T_g increase is directly related to the chlorine content. CPVC can be used directly or in completely miscible blends with PVC to obtain products having higher T_g s.

Heat-resistant blends can also be obtained by blending PVC with α-methylstyrene – acrylonitrile copolymer (see Section 4.3) which is completely miscible with PVC. Blends are also available with a low T_g. An important example is the blend of PVC with NBR rubber; depending on the nitrile content (critical level, 32 wt % acrylonitrile) a single-phase soft blend or a two-phase impact-modified PVC can be made.

Impact performance can be improved by blending with two-phase impact-modified materials such as ABS and ASA (acrylonitrile – styrene grafted onto acrylic rubber). ASA does not impair weatherability as is the case for ABS. Blends with poly(methyl methacrylate)(PMMA) also show good weatherability performance. Blends of PVC with ABS, ASA, SMA, and PMMA are mainly applied as structural panels in the building industry. The blends are extruded in sheets which are shaped by vacuum forming and press molding. The PVC provides mechanical strength and flame resistance. The second component should provide the required heat distortion temperature and surface properties. The impact modification of PVC and its blends has been increased by using shell – core impact modifiers [41]. These modifiers consist of a very small rubber core, usually a butadiene homo- or copolymer or a poly(butyl acrylate) copolymer, and a "hard shell" made of PMMA or SAN. The shell polymers should have optimal interaction with the matrix PVC. These impact modifiers are not only very effective but also allow high shear processing without deterioration of surface appearance.

Since 1980, PVC and its blends have been able to penetrate the injection-molding market. This was made possible by (1) improving the flowability of PVC by an order of magnitude via reduction of its molecular mass, (2) a greatly improved stabilization package, and (3) improved thermal control in modern molding machines to prevent overheating.

The construction and pipe markets are supplied by PVC – chlorinated polyethylene blends (preferred in the United States) and PVC/EVA blends (preferred in Europe). Both blends have better impact properties than PVC. EVA blends have a slightly better UV stability.

PVC – polyurethane blends are typically used in shoe soles, boots, oil-resistant articles, and calendered coatings by virtue of their UV stability, better thermal stability, and low temperature flexibility.

The additions of small amounts of methyl methacrylate (MMA) copolymers to PVC improves its hot melt strength and reduces melt fracture during processing. Toughness and impact performance can be further improved by blending with MMA- containing impact modifiers. Applications include clear films and window profiles.

4.3. Styrene Polymers and Copolymers

See also → Polystyrene and Styrene Copolymers.

Polystyrene. Polystyrene [*9003-53-6*] (PS) is a very brittle polymer (T_g 100 °C) due to a low entanglement density and lack of secondary transitions. Its usefulness has therefore been limited severely. Poor impact performance has been a major concern and was originally addressed by blending PS with styrene – butadiene (SBR) rubber and subsequently by the now generally established chemical processes for making high-impact PS (HIPS). The block copolymer styrene – butadiene (SB) and terpolymer styrene – butadiene – styrene (SBS) as well as their hydrogenated derivatives, are used as blend components to improve impact properties [36]. The resulting deterioration of the continuous use temperature (T_g reduction by at least 10 °C) can be solved by either making copolymers of styrene with stiffer or more polar comonomers such as α-methylstyrene, maleic anhydride, acrylonitrile, or by blending with a miscible high-T_g polymer such as poly(tetramethylbisphenol A carbonate) or PPE (see Section 4.5). Blending relatively small percentages of PPE ($< 30\,\%$) with PS can be important because it increases the heat distortion temperature by about 1 °C per percent PPE. The mechanical deformation behavior of the blends is also greatly improved by the strong increase in the overall entanglement density. The overall property profile of pure PS is not good enough to make it an interesting blend component for a two-phase system.

PS – polyolefin blends have been developed for packaging purposes bringing the combination of printability, fat resistance, and barrier properties. They again have a controlled delaminated morphology and are typically extrusion materials. However, the more polar and functionalized PS copolymers offer far better blend possibilities and are widely used and discussed below.

ABS. See also → Polystyrene and Styrene Copolymers, Chap. 5. Most commercial acrylonitrile – styrene – butadiene polymers [*9003-56-9*] (ABS) are blends of rubber-impact-modified styrene – acrylonitrile (SAN) copolymer with SAN or other SAN-miscible copolymers. Blending can take place in a suspension or emulsion by coagulation or melt blending during the compounding phase. ABS can be produced by three different techniques: emulsion, suspension, and mass (bulk) polymerization [42], [43]. Each technique delivers ABS with slightly different properties.

The main properties of ABS resins are their good to very high impact strength and low price, coupled with very acceptable mechanical (engineering) properties up to 90 °C. They have an excellent surface appearance and good chemical resistance. In addition, they possess the excellent injection-molding behavior of PS, good melt flow, low mold shrinkage, and an excellent surface finish. Their main disadvantage is their poor resistance toward prolonged exposure to light and heat due to the unsaturated bonds in the butadiene rubber impact modifier systems. UV resistance can be improved by incorporation of acrylic rubbers (ASA). Principal advantages of ASA (SAN grafted onto acrylic rubber) over ABS are high outdoor stability, high resistance to yellowing on exposure to UV light, and good resistance to environmental stress cracking [43]. Other essentials of ABS are its composition-dependent T_g (100 – 120 °C) and a continuous use temperature between 80 and 100 °C. The actual use temperatures for ABS can be en-

hanced up to 118 °C through the incorporation of α-methylstyrene. Its high flammability can be improved by addition of 10 – 15 % bromine-containing compounds and 3 – 5 % antimony trioxide. This results in a higher density, reduced color intensity, lower surface properties, reduced impact performance and processibility, and corrosivity. Blending is a preferred method used to increase the heat distortion temperature, to improve weatherability (unsaturated impact modifiers), and overcome flammability concerns.

ABS – PC and ASA – PC Blends. These blends offer a somewhat higher heat distortion temperature than ABS and good processing characteristics [43–45]. The Vicat softening temperature of 100 °C for ABS can be raised to 130 °C by blending with PC. The carbonate group of the PC and the nitrile group of the SAN matrix interact [46], providing just enough compatability for a useful blend. Optimum interaction between the polymers is obtained for a SAN containing 30 wt % acrylonitrile [46]. Intrinsic compatibility can be enhanced through addition of a third component containing ester groups (e.g., PMMA or PBT) [47], an effect that can be explained in terms of mutual miscibility.

ASA – PC blends offer a better resistance towards UV light and heat aging compared to ABS/PC (Fig. 12). Applications include instrument panels, distribution boxes, and kitchen exhaust hoods [48].

Figure 12. Failure energy of ASA – PC and ABS – PC as a function of the duration of exposure to heat

ABS – PVC Blends. ABS has excellent surface properties with high gloss, but burns readily and completely. PVC (T_g 85 – 95 °C) on the other hand lacks the good impact behavior and processibility of the styrenics. An excellent interaction exists between PVC and ABS, removing the need for compatibilizers. ABS – PVC blends are used in low-cost electrical panels such as covers and enclosures [7].

SMA – ABS Blends. Copolymers of styrene and maleic anhydride (SMA) have glass transition temperatures ranging from 100 to 140 °C, depending on the maleic anhydride content. The materials are rather brittle, but impact-modified resins are known. Impact performance can be improved by blending with ABS. Both resins are compatible and have a good processibility (styrenics). The miscibility window is remarkably small considering the similarity in structures [49]. Instrument panel frames is a large automotive application.

ABS – PA Blends. Both chemical resistance and heat distortion temperature can be improved by blending ABS with semicrystalline polyamides. Typical applications are automotive body panels, connectors, and under-the-hood components [7], [48]. See also Section 4.4.

4.4. Polyamides

Polyamides (PA) are either semicrystalline or amorphous. The polymer chain can consist of aliphatic, cycloaliphatic, and aromatic components. More than 60 different commercial polyamides are known. For further details, see → Polyamides.

Examples are included of the two most important general-purpose polyamides: (1) PA 6 [*25038-54-4*] made by ring opening polymerization of ε-caprolactam, and (2) PA 66 [*32131-17-2*] made from hexamethylenediamine and adipic acid. These aliphatic PAs are mostly used for their combination of wear resistance strength, chemical resistance, creep resistance, and low coefficient of friction. Good dimensional stability can only be obtained for (glass) filled materials which have the disadvantages of warpage and machine wear. Polyamides have a good strength and fatigue resistance. Tensile modulus values of the matrix can be increased by incorporation of aromatic monomers in the main chain. The fully aromatic PAs have a high intrinsic flame retardance.

Decomposition tem-peratures for most aliphatic and aliphatic – aromatic PAs, are 280 – 300 °C, limiting the processing temperature.

The properties of PAs are highly dependent on the interactions of the polar amide linkage. Higher-melting PAs can be obtained by increasing the frequency of amide linkages [50]. The amide linkage interaction between the polymer chains in the crystal structure via hydrogen bonding is particularly strong in the amorphous phase. It also causes water absorption which is related to the methylene – amide ratio. Water absorption decreases the dimensional stability of the polymer, reduces the T_g (plasticizing effect), but increases the toughness. The magnitude of the T_g reduction with respect to relative humidity changes depends on the amount of amide linkages and stiffness of the chain. A major drop in tensile modulus at room temperature results when the T_g drops from 50 to below 0 °C. Other physical properties (e.g., dielectric constant, water permeability) also change considerably.

There are three major reasons for blending PAs:

1) To increase their heat distortion temperature (in a conditioned state)
2) To reduce their moisture sensitivity and thus enhance dimensional stability
3) To improve their dry impact strength (at low temperatures)

Polyamides are very suitable for in situ compatibilization techniques (reactive extrusion) due to the presence of reactive amine or carboxyl end groups. Carbonamide groups are also available for hydrogen bonding.

PA – PA Blends. Melting points of semicrystalline PAs are sometimes very close to their degradation temperatures, creating either a very small or no processing window. Blending aromatic semicrystalline PAs with aliphatic PAs improves their processibility. Aliphatic PAs generally have lower T_gs, but a higher water absorption value which can lower the T_g in the dry state significantly. Aromatic PAs possess more free volume, and have a lower dimensional growth with the same water absorption.

Blends of amorphous transparent PAs have been reported [51]. Predictions of miscibility windows between PAs using binary interaction and intramolecular repulsion models proved that the amide concentration was more important than compositional differences [52–54].

PA – ABS Blends. Blends of PA 6 and PA 66 with ABS combine chemical and abrasion resistance with high impact resistance. The ABS phase provides good dimensional stability up to 90 °C that can be further improved by substitution of styrene in the ABS with α-methylstyrene [55]. These blends are also more warp resistant due to the reduced (semi)crystalline volume fraction. Compatibilization is achieved through hydrogen bonding between amide NH and nitrile CN groups. Anhydride-containing polymers such as SMA have been used to improve compatibilization by covalent bonding and to obtain a smaller particle size [56].

Triax 1000, (Monsanto) is an example of a PA – ABS blend. It is used for a variety of markets such as functional (mainly under-the-hood) automotive components, power tools, appliances, and sports goods. PA – ABS blends have excellent chemical resistance, stress resistance, and toughness due to their co- continuous network.

PA – PC Blends. Blends of PA 6 and PC have been investigated over the full range of compositions, and proven to be immiscible [57]. Chemical reactions are claimed to produce low molecular mass compounds that both plasticize and slightly compatibilize the blend. No commercial PA – PC blends have yet been developed.

PA – PP Blends. Blending PAs with PP raises impact strength, solvent and moisture resistance, and improves strength [34]. The addition of compatibilizers and/or glass fibers is required to obtain a blend with a stable morphology. Compatibilizers are formed in situ by using maleic anhydride-functionalized styrene – ethylene – butadiene – styrene (SEBS) triblock copolymers [58], [59], ethylene – propene copolymers, PP, HDPE, or glycidyl methacrylate copolymers [60] in concentrations of 1 – 30 wt %. Maleic-anhydride-modified compatibilizer intermediates yield a better dispersion (with particle diameters in the range 0.1 – 0.3 μm) and high impact values. Interestingly, material toughness is not enhanced by using smaller rubber particles [59].

PP is usually processed at 200 °C, but PA – PP blends are processed at 250 °C – the presence of PP leads to a readily flowing resin. These resins are used for decorative applications where dimensional stability is much more important than mechanical properties. Examples include automotive applications, sprinkler housings, and housings for industrial tools.

Impact-Modified PA. The notch sensitivity of most PAs can be reduced by blending with 20 – 30 % functionalized impact modifier such as maleic-anhydride-functionalized HDPE [61], [62], or maleic-acid-modified EPDM rubber. PA 66 has an intermediate level of ductility, characteristic of a semicrystalline resin. Chain mobility is reduced by the presence of crystalline regions and relaxation times of polymers are increased. Impact modifiers are used to create overlapping stress fields (optimum conditions at 30 vol % impact modifiers) which enhance ductility [61]. Good adhesion is provided by the maleic anhydride functionalities on the impact modifiers.

The materials are used for all applications where ordinary PAs fall short of required impact strength and toughness: oil pans, fan blades, connectors, and power tool housings.

4.5. Poly(2,6-Dimethyl-1,4-phenylene Ether)

Poly(2,6-dimethyl-1,4-phenylene ether) [25134-*01-4*] (PPE) and its blends have been extensively reviewed elsewhere, → Poly(Phenylene Oxides), but will be briefly summarized. PPE is an amorphous resin (T_g 215 °C) with a number of attractive properties [63]. It has a serious drawback however: its (melt) processing temperature is higher than temperatures at which severe side reactions take place, thus altering the polymer property profile.

PPE – HIPS Blends. The full miscibility of PPE with PS, discovered in the early 1960s [64], [65], led to the development of blends with lower (and thus acceptable) processing temperatures. Polystyrene has a low T_g and good melt processibility.

PPE – PS blends are fully miscible over the complete composition range as illustrated by a single T_g for each composition. This provides the end user with a tremendous flexibility in achieving required maximum use temperatures. Resulting heat distortion and Vicat B temperatures are discussed in [63], → Poly(Phenylene Oxides), Chap. 3.1.

The miscibility of PPE with styrene copolymers and polymers of styrene derivatives, e.g., poly(α-methylstyrene) [64–66] has been studied. Many of these blends also demonstrate full miscibility, probably due to the interaction of the electron-deficient methyl groups of PPE with the electron-rich phenyl rings of PS [63], [67]. The reduction of impact performance of the ductile PPE by blending with brittle PS (Fig. 13) can be attributed to a reduction of the entanglement density and some loss of free volume [63], [67]. Impact performance is greatly improved by incorporation of impact modifiers. Thermograms of commercial blends have two glass transition temperatures, with one of them being attributable to the rubber impact modifier [68].

Figure 13. Impact strength of PPE – PS blends as a function of temperature
a) PPE; b) PPE – PS (70 : 30); c) PPE – PS (30 : 70); d) PS

Impact strength increases with PPE molecular mass. Commercial PPEs have weight-average molecular masses in the range 30 000 – 40 000. The rubber particle size is also important. Since their commercial introduction in 1964 by General Electric, PPE – HIPS blends have become the engineering polymer blends with the largest annual sales. They are used for applications ranging from automotive interior parts including dashboards and instrument panels, to business machine housings and chassis; from electrical conduits and lighting covers to gears and sprockets.

a) PPE – PA 66, 1 h; b) 100 h; c) 5000 h; d) PA 66 1 h; e) 100 h; f) 5000 h

PPE – PA Blends. PPE – PA 6 and PPE – PA 66 blends have been extensively discussed elsewhere, see → Poly(Phenylene Oxides), Chap. 3.2. In these blends, the finely dispersed PPE phase raises the continuous use temperature. The tensile modulus is maintained up to almost 205 °C with only a minor drop over the temperature range from 0 – 50 °C due to the T_g of the amorphous PA phase. The moisture sensitivity of the system is also reduced. The PA 6 and PA 66 phases provide easy processibility and chemical resistance. These PAs can be easily replaced by PAs with higher glass transition and melting temperatures [69–71]. Rubbery impact modifiers have been added to improve low-temperature impact performance [69–71]. These blends exhibit mechanical properties which are less moisture-sensitive than PA 66 as shown by the stress – strain curves (Fig. 14). At a stress level of 7 MPa, PA 66 exhibits three times as much creep as the PPE – PA 66 blend.

Blends of PPE and PA have been specifically developed for exterior automotive parts with a Class A surface quality (e.g., fenders of the Renault Clio 16 S). Other applications are rear quarter panels, and hood materials for lawn and garden tractors.

PPE – Polyolefin Blends. The usefulness of unmodified PPE is limited by its notch sensitivity and difficult melt processibility. Addition of polyolefins improves flow by modifying the melt rheology of the system but sometimes lowers the heat distortion temperature. New blends have been developed in which PPE is combined with special rubbers (e.g., high molecular mass polyoctanomer [72], [73]) that have a high impact strength, a high softening temperature up to 205 °C, and facile processibility. These PPE – polyolefin blends have a high gloss and are used in metallizable head lamp reflectors. Other application areas are dimensionally stable exterior automotive body panels, and major appliances.

The intrinsic flame retardancy of PPE has been enhanced with additives resulting in a new, halogen-free, flame-retardant material that meets the most stringent low smoke [73], low toxicity, and low corrosivity standards. The key factor is increased char formation under fire conditions which reduces the amount of volatiles [73]. Potential applications of this material (Noryl Xtra LS) are in office buildings, trains, and tunnels.

Figure 15. Blend motives for PC and PBT

4.6. Polycarbonates

The polycarbonate of bisphenol A [*25037-45-0*] (PC) is a linear polymer with a low rate of crystallization. See also → Polycarbonates. Thus, it is regarded as an amorphous polymer (T_g ca. 145 °C). Its maximum use temperature is approximately 130 °C and, because of its excellent thermal oxidative stability, this almost coincides with its continuous use temperature (125 °C). PC is noted for its high impact resistance, especially at low temperature. This is due to the high segmental mobility of the polymer chain (gamma transition at − 100 °C [74]). Polycarbonate suffers from stress – crack sensitivity coupled with poor chemical resistance. The latter prevents PC from being used in automotive applications where frequent contact with gasoline and oils would ruin its material properties. Chemical resistance can be improved by blending with semicrystalline polyester resins. The stress cracking sensitivity of PC can be overcome by blending with ABS or ASA.

Figure 16. Dynamic mechanical properties of PC, PBT, and PC – PBT blends : shear modulus (— — —) and mechanical loss factor (— — —) as a function of temperature
a) PC; b) PBT; c) PC – PBT (55 : 45)

PC – Polyester Blends. The advantages resulting from blends between PC and PBT are summarized in Figure 15. Blends of PC with polyesters are based on a partial miscibility of both components in the amorphous phase [75–77]. Thermal and dynamic mechanical analysis shows a sharp T_g transition for PC at 150 °C (Fig. 16), and a sharp melting point at 225 °C with a broad glass transition for PBT due to the spectrum of relaxation times of the crystal – amorphous polymer interphase. Partial miscibility of PC and PBT is indicated by a shift of the PC T_g to 141 °C in a PC – PBT blend.

Blending both resins results in a complex co- continuous morphology. Resistance towards chemicals (e.g., oils and lubricants) is strongly enhanced as compared to PC. However, the impact properties of these blends are still insufficient for automotive applications. Impact modification with a rubber compound (frequently core – shell impact modifiers) solves this problem [78], [79].

The key to morphology control and thus mechanical properties is control of transesterification. Care should be taken to prevent these reactions (Figs. 17 and 18) catalyzed by residual polycondensation catalysts present in the PBT [79–81]. Addition of proprietary additive packages is commonly practised. In addition, processing temperatures of 270 – 290 °C should not be exceeded.

One of the most successful applications of the blend of PC, PBT, and impact modifier (Xenoy, GE Plastics) is a car bumper, developed for the Ford Sierra in Europe, and transferred to the Ford Escort in the United States. This bumper withstands 5 km/h impact at high and low temperature.

PC – PETP blends have similar properties to their PBT analogs [7], [82], [83]. The lower crystallization rate of PETP allows the development of transparent materials for use in medical applications by virtue of their good dimen-

Figure 17. Ester interchange between PC and PBT

sional stability, clarity, and low water absorption. The products have a better chemical resistance than PC and are impact modified to give acceptable low-temperature impact performance. PC–PETP blends flow better than PC, and are injection-moldable. Unreinforced PETP cannot be injection molded due to its low rate of crystallization.

Figure 18. Morphology of impact-modified PC – PBT blend (Xenoy, GE Plastics)
The darker areas are PC, the black dots are impacted modifiers, the remainder is PBT.

PC – Polyolefin Blends. Despite its good toughness, PC has a distinct ductile to brittle transition which is dependent on temperature, thickness, test speed, stress configuration, and molecular mass. The dependency is reduced if PC is blended with low levels (4 – 8 %) of LDPE. This shifts the ductile – brittle transition of PC from about 0 °C to below − 20 °C. Moreover, the effect of part thickness on notch Izod impact strength is reduced [84].

PC – ABS Blends. Polycarbonate blends with ABS resins have been successfully used in automotive interior and exterior applications [43], [85]. The acrylonitrile content of the ABS plays a key role in determining the miscibility of the SAN phase with the PC phase. ABS has no low-temperature impact performance, whereas PC does through its gamma transition at − 100 °C and ample free volume [74]. The impact values of PC – ABS blends are directly correlated with their heat distortion temperatures. The presence of the rubbery impact modifier slightly reduces the tensile modulus. The HDT values are hardly affected at modulus values above 3 GPa. These are important values because they are required for high-speed impact tests for automotive applications. In addition, PC – ABS blends provide paintability and better UV stability if PC is the continuous phase [86–89]. The addition of UV absorbers to the (transparent) PC phase improves the protection of ABS against the damaging effects of UV light (see Section 4.3). PC–ASA blends have superior weather resistance, however.

PC – ABS swells in aromatics, ketones, esters, and hydrocarbons. It has good electrical insulating capability. Major applications are instrument panels [7] and business equipment housings [90].

4.7. Polyesters

Thermoplastic polyesters have a low moisture absorption and are chemically resistant apart from being susceptible to hydrolysis at high temperature in alkaline environments. They have a low dimensional stability due to their low T_g; glass-filled materials are required to achieve acceptable use temperatures. Impact performance for these highly filled materials is poor, but can be improved by blending with impact modifiers. The most important polyesters are poly(ethylene terephthalate) [*25038-59-9*] (PETP) and poly(butylene terephthalate) [*24968-12-5*] (PBT). See also, → Polyesters PBT crystallizes within 1 – 3 s whereas PETP crystallizes within 15 – 20 s. PBT's higher melt flow and faster crystallization lead to a shorter cycle time. Special processing conditions are required if (partially) crystalline PETP is to be obtained: high mold temperature (120 – 140 °C) and long cycle times (2 min). The advantages of PETP over PBT are its higher melt temperature (256 vs. 226 °C) and strength.

PBT – PETP blends have enhanced surface quality and reduced warpage when reinforced with glass fibers. Both qualities are attributable to the lower rate of PBT crystallization caused by the addition of PETP. The weight ratios used in PBT – PETP blends are usually 85 : 15 to 75 : 25. HDT values are not affected, but costs are reduced due to the lower price of PETP. Typical ap-plications include hot-appliance housings (e.g., toasters, irons, and frying pans).

PBT – PC Blends. Addition of PC to glass-filled PBT grades increases impact strength values and improves thermal expansion, flow, and flatness (reduced warpage). The chemical resistance of these blends is slightly lower than that of a PBT compound. Core – shell impact modifiers are used for toughening [78], [79], [91]. The importance of interfacial adhesion with the matrix has been proven [91], [92]. Applications include grill doors, air cleaners, and appliance components where improved dimensional stability over PBT is required.

Miscelleneous Polyester Blends. Noteworthy are blends of PBT with copolyester elastomers containing short crystallizable PBT blocks [93]. The tensile strength and modulus of these compounds are increased upon blending with PBT while retaining its flexibility. Excellent surface quality and improved paint adhesion qualify these resins for bumper fascias. Similar uses hold for PETP – acrylic and PBT – acrylic materials. Toughened PBT and PETP blends are used to extend existing product lines by varying the amount and type of impact modifier. Ignition compounds, housings, and windshield wipers are typical automotive applications; flame-retardant grades are used for connectors and switches.

4.8. Polyetherimides

Polyimides are condensation polymers derived from bifunctional carboxylic anhydrides and primary diamines. Polyetherimides [*61128-24-3*] (PEI) contain an ether group in either or both the aromatic dianhydride or aromatic diamine building block. Ultem polyetherimide (GE Plastics) produced from bisphenol A bisether dianhydride is the only commercially available thermoplastic polyetherimide [94] (see also → Polymers, High-Temperature, Chap. 2.2.). It has a glass transition temperature of 217 °C, and can be subjected to conventional melt-processing techniques. Its thermal stability is maintained up to ca. 500 °C under nitrogen [95].

In commercial PEI grades, additives (e.g., reinforcing fibers) and modified base resins are used to increase the glass transition temperature and chemical resistance. Primary reasons for blending are therefore to improve processibility, impact strength, and chemical resistance. PEI is used mainly in under-the-hood automotive applications, head-lamp reflectors, injection-molded printed circuit boards, trays for microwave ovens, and high-performance composite sheets with PEI as the matrix.

PEI – PC Blends. PEI – PC blends combine the high temperature resistance and intrinsic flame retardance of PEI with the good impact performance and ease of processing of PC. Interactions are strong enough to form an excellent blend without using compatibilizers. The high continuous use temperature of PEI is not decreased because PC is stable to thermal oxidation up to ca. 175 °C. Blending with PC reduces the price of the material and its notch sensitivity.

Two grades of PEI – PC thermoformable sheets exist, one is targeted to household applications (e.g., Tupperware microwave cookware), the other to aircraft interior components where the material satisfies all regulations pertaining to flammability, smoke, and toxicity. PEI – PC is used for aircraft window housings and seat backs.

Thermoformable PEI – PC products are also used as high-temperature paint masks in the automotive industry to prevent overspray. The high heat resistance and excellent dimensional stability enable the material to withstand the temperature conditions in the painting operation.

PEI – PEEK Blends. PEI is an amorphous resin. Its chemical resistance can therefore be improved by blending with a semicrystalline resin. PEI is miscible with the amorphous phases of polyetherketone [*27380-27-4*] (PEK) and polyetheretherketone [*31694-16-3*] (PEEK) over the entire composition range. Crystallinity

and crystallization are not affected by incorporation of up to 40 wt % PEI [96]. The product range of these materials can be further enlarged by copolymerization of the PEI structure leading to enhanced inherent properties.

Markets for PEI – PEK and PEI – PEEK blends have not yet been fully exploited [97]. A 70 : 30 PEI – PEEK grade developed by Amoco Performance Polymers was not commercialized due to competition with the liquid crystalline polymer Xydar [7].

4.9. Polysulfones

Polysulfones [*25135-51-7*] (PSU) and polyethersulfones [*25667-42-9*] (PES) are amorphous high-T_g polymers with excellent thermal and oxidative stability (see also, → Polymers, High-Temperature). Their environmental stress-cracking resistance against most liquids encountered in the food and automotive industries is good because of the polar sulfone group.

Polysulfones are, however, expensive, demonstrate a severe notch sensitivity, and have a limited chemical resistance resulting in stress cracking sensitivity under certain conditions. Both problems can be overcome by blending with ABS (Fig. 19), PAs, PETP, and PBT. Chemical resistance is strongly improved if the semicrystalline resin constitutes the continuous phase. The principles and objectives followed for developing these blends are the same as those for PC – ABS, PC – PETP, and PPE – PA blends. Polar interactions are possible between the carboxyl groups of PSU and the nitrile groups of ABS.

Applications include household water faucets, electric, and electronic applications. PSU – PBT replaces PBT in selected connectors and switches due to its higher strength [7], [48].

4.10. Polyoxymethylenes

Polyoxymethylene [*9002-81-7*] homo- and copolymers are highly crystalline materials well known for their hardness, low friction coefficient, chemical stability, and relative brittleness; see also → Polyoxymethylenes. They are highly flammable (LOI 16) and their thermal stability is limited to 210 °C. In view of their melting temperature of 182 °C (homopolymer), careful processing is required.

Blends of polyoxymethylene homo- and copolymers are known. Silicone oils and polytetrafluoroethylene have been added to POM to enhance the high slip characteristics. Impact-resistant grades of POM use polybutadiene, acrylic rubber, grafted synthetic rubber, polyolefins, and polyurethane [98].

Impact-resistant POMs, comparable to supertough nylon, have been produced by blending with compatible linear thermoplastic polyurethanes. They demonstrate a special morphology since the polyurethane phase forms an interpenetrating network structure in the POM matrix.

Applications are hinges and connectors that demand improved low-temperature flexibility and impact strength.

4.11. Polyarylates and Copolyarylate – Carbonate Blends

In principle the polyarylates (PAr) comprise all fully aromatic polyesters. In practice this term denotes polyesters derived from bisphenol A and mixtures of isophthalic and terephthalic acids in ratios between 70 : 30 and 30 : 70, but most frequently 50 : 50 [99], [100]. Due to their fully aromatic structure, the PArs are amorphous, transparent, practically colorless, and heat resistant. The T_g of the commonly used PAr containing bisphenol A and isophthalic/terephthalic acid in a weight ratio of 50 : 50 is 184 °C. This polymer is soluble in chlorinated hydrocarbon solvents, has a reasonable hydrolytic stability, good mechanical properties, strength, modulus, impact resistance, and excellent weatherability (despite yellowing). The polyarylates are intrinsically self extinguishing in flammability tests [101], [102]. Processibility is, however, marginal in view of the high processing temperatures (320 – 360 °C) required. Copolyester carbonates (PPCs) have therefore been developed with T_g's between those of PC (145 °C) and PAr (184 °C). PPCs are aromatic copolyesters in which part of the ester groups are substituted with carbonates. This group of polymers fills the T_g gap which existed between PC and the polysulfones [103].

Figure 19. Blend motives for PSU and ABS

Polyarylates are mainly used in applications demanding high heat stability and transparency such as lenses and medical equipment (high-pressure steam and radiation resistance needed for sterilization). Since the ultimate thermal dimensional stability of polymers under loading conditions is determined by the T_g of the matrix polymer, polyarylates and copolyarylates contribute significantly to the engineering property profile of blends.

Many PAr blends, especially those with semicrystalline aliphatic – aromatic polyesters such as PETP, PBT, and poly(cyclohexane terephthalate) (PCHT) have been made but very few have been successful. These polyester – PAr blends show the same features as the polyester – PC blends. PETP and PBT blends are partly miscible with PAr, whereas PCHT is completely miscible over the whole composition range. Furthermore, under melt-processing conditions, transesterification reactions catalyzed by polymerization catalysts rapidly transform the physical blend into a homogeneous copolymer with an averaged T_g value. Only by adding phosphites can the catalytic system be deactivated, yielding a usable blend with different characteristics from the existing PPCs. This holds particularly for the PETP and PBT blends. The ester interchange reaction does not need to be stopped in PAr – PCHT blends due to its complete miscibility [104–107].

PETP – PAr blends are used in the automotive industry for their improved chemical resistance and heat distortion temperature over PC and PC – PETP blends. They are also used in the lighting industry for reflectors. PCHT – PAr blends are used in medical applications because they have a very good resistance to yellowing when exposed to high-energy radiation for sterilization [103].

4.12. Poly(Phenylene Sulfide)

Poly(phenylene sulfide) [*9016-75-5*] (PPS) is a versatile thermoplastic engineering resin (see → Polymers, High-Temperature, Chap. 5.). It possesses high temperature resistance, inherent flame resistance, good mechanical properties, and high chemical resistance. The mechanical properties and dimensional stability of parts are determined by the crystallinity and orientation of the polymer during processing. Unfortunately, PPS is very brittle resulting from stiff spherulites and weak interspherulitic boundaries. Research is therefore directed at improving ductility while maintaining overall crystallinity levels.

Two types of PPS are commercially available: (glass) filled grades and blends with polytetrafluoroethylene (to improve moldability and crack resistance). A large number of other blends have been reported (e.g., PPS – PEI [108] and PPS – PETP [109]) but have not been introduced commercially.

5. General Application Technology

5.1. Processing of Blends

The utilization of thermoplastics, including blends, involves processing and adjustment of the bulk rheological properties of each commercial plastic grade to the requirements of the processing technique (e.g., injection molding, extrusion, blow molding). Adjustment is only possible if an acceptable processing window exists within the molecular mass constraints of the polymers which are needed to obtain the desired mechanical properties. The processing window is determined by the thermal stability and the processibility (viscosity) of the melt. In blends, the maximum melt temperature is determined by the stability of the least stable component.

The rheology of a blend system is determined by its components. Blend processibility can only be predicted to a limited extent. The rule of logarithmic additivity only applies to completely miscible systems of homologous polymers such as mixtures of the same polymer with different molecular masses (Eqs. 10 and 11), all functions having a molecular mass > entanglement molecular mass.

$$log\eta_b = \Phi_1 \log\eta_1 + \Phi_2 \log\eta_2 \tag{10}$$

$$\eta_b^{1/3.4} = \Phi_1 \eta_1^{1/3.4} + \Phi_2 \eta_2^{1/3.4} \tag{11}$$

where η is the viscosity, Φ is the partial volume, and the subscripts b, 1, and 2 denote the blend, component 1, and component 2, respectively.

Even for a completely miscible blend system (e.g., PPE – PS), corrections have to be made for the "positive deviation" which is associated with the mixing enthalpy (Eq. 12):

$$\log\eta_b = \Phi_1 \log\eta_1 + \Phi_2 \log\eta_2 - \frac{\Phi_1 \Phi_2 \Delta H_{\text{mixing}}}{2.45RT} \tag{12}$$

This enthalpy factor depends on the temperature (LCST behavior, Section 3.1). In miscible or partly miscible blends with processing temperatures close to the LCST temperature this can have extremely important effects, such as shear-induced phase separation (temperature rises due to the introduction of mechanical energy via the processing equipment) leading to complete loss of morphology and mechanical properties. Furthermore, the elastic and viscous parameters that depend on temperature and shear rate also contribute to the rheology characteristics of a polymer, and are different for each polymer.

In impact-modified multiphase blend systems, the prediction of the rheology characteristics by means of (empirical) rules becomes highly unsatisfactory. Simple approaches based on the Einstein relation for dispersions of solid particles in a liquid are followed by assuming that two-phase systems behave as a dispersion of fixed particles of different deformability (from solid to rubbery). In more complex two-phase blends where the morphology of the dispersed phase is not fixed and delamination is possible, a combination of parallel and series model of rheological effects is used with an interfacial layer correction.

The impact modifiers interact strongly with the matrix to create a thixotropic melt behavior in which the viscosity value at zero shear rate is much higher than in the unmodified systems. These characteristics can be very useful in creating the higher melt strength needed for extrusion and blow molding. Their presence may, however, also lead to poor surface appearance and knitline problems under excessive shearing forces.

In conclusion, the rheology of polymer blends is extremely complicated to predict, but commercial products are tuned to the requirements of most standard processing methods. The tolerance level for deviation from the recommended processing conditions is not unlimited.

5.2. Design Technology

The design considerations of a thermoplastic part involves functional factors related to production and assembly, and material factors related to the performance of a material in service.

Design procedure can be subdivided into the selection of the production process (e.g., injection molding, extrusion), resin characteristics (mechanical and electrical properties), flow analysis, stress analysis, long-term considerations (creep, fatigue, stress relaxation), appearance of a part, its assembly (including automation), and recycling. Computer programs aid the designer in developing a part capable of meet-

ing all the mechanical requirements, while maintaining its production feasibility [28], [110].

The current emphasis on recycling demands that produced parts can be easily disassembled from final applications. In the case of cars, routes for facile dismantling and separation should be conceived in the designing step (see Section 6.1). Product designers and engineers must therefore consider all aspects of the primary and secondary life cycles.

Blends require special consideration of flow (viscosity), weld lines, processing temperature versus phase behavior (see Section 3.1), flow versus continuous phase, and high shear conditions. Thermodynamically controlled, shear-induced phase separation is possible leading to delamination and morphology changes (Section 5.1). Care should be taken to avoid high shear conditions.

The dependence of viscosity and shear rate on temperature is also very important for blends because the ratios between the blend components influence blend morphology and determination of the continuous phase (see Section 5.1). Prediction of rheology and flow behavior is more complicated than for single thermoplastic resins. Weld lines are an issue at positions where two flows encounter each other [111]. Design should result in placing weld lines in nonstressed regions.

6. Future Developments

6.1. Recycling

Recycling of plastics and polymer blends has drawn public attention, see also → Plastics, Recycling. Concern regarding plastic waste has risen because of the large volume of plastics (20 – 30 %) in municipal waste. It corresponds, however, to a weight fraction of only 8 % for which packaging materials are mainly responsible. The volume of waste must be reduced, particularly in densely populated areas. Thermoplastic blend producers and end users are faced with finding commercially effective recycling strategies. This is particularly acute for the automotive industry in Germany, where recycling laws demand the recycleability of 25 % of plastic car parts by the end of 1994.

The use of smaller quantities of better, more durable blend products may or may not have a positive overall environmental effect. One of the solutions to the waste problem practised in Japan is energy recycling by burning (70 %) and deposition of solid waste (30 %). This simple solution will soon disappear in the western world for political and economic reasons – waste disposal will become very expensive due to increasing tariffs. Other options (i.e., reuse of plastics in other applications) must therefore be considered.

The most important factor in plastic recycling is the purity and compatibility of the waste. Minimum waste is generated in plastic manufacturing and compounding facilities due to economic reasons; reworking of plastic waste is a standard procedure. Separation of the different plastics used facilitates backfeed and rework programs. Multilayer coathanger extrusion and two-component molding facilitate the usage of off- color and slightly off-grade materials.

The real problem starts with postconsumer plastic waste where purity and compatibility requirements are no longer fulfilled. Separation, sorting, and cleaning of the plastic waste from the bulk waste are necessary. This is very expensive and only economically feasible for a small number of cases. Any recycled material derived from plastics with different colors and grades therefore represents a downgrade product. In addition, this approach will only succeed if the recycle concept is economically viable, e.g., in the case of high-value engineering plastics.

Reusing the chemicals from which the polymers were made is another route. Thermal, pyrolytic, hydrolytic, or glycolytic processes are used to degrade the polymers [112]. This approach is only applicable in a few cases and has been proven technically feasible with PETP bottles [112]. However, the process economics are very limited.

Finally, the fuel value of the plastics should be considered. Polymers have a considerable caloric value being (mainly) organic materials. The energy in the material can be reclaimed by burning and then converted to electrical energy or steam.

Already 20 % of all plastics used can be considered blends. Blend thermodynamics, morphology, and careful processing are critical for obtaining the required/desired mechanical

properties (Chap. 3). Lower-grade applications should be found for recycled blends. Typical examples are blends of postconsumer PE with PA 6 [113], scrap rubber [114], and recycled PETP with PE [115], [116] and PC [117].

Two important principles govern the role of engineering blends in recycling strategies:

1) Designing and developing better, more durable products via blend technology.
2) Combining compatible resin systems (i.e., minimization of the number of different resins in a module for various applications). The target is to obtain materials from one product family which are mutually compatible (Section 3.2). Only these compatible materials can be combined to yield economically viable, useful materials (Fig. 20).

An example of a module is a dashboard structure made of a glass-filled, injection-molded PPE – HIPS blend, which could include, for example, a large proportion of recycle material from dashboards. The air ducting is made of compatible, blow-molded PPE – HIPS and is mounted on the carrier unit by means of PPE – HIPS clip fasteners. The complete unit is overmolded in PPE – PS foam to form the outer surfaces and to provide sound insulation. A soft-feel foil is used to give a "luxury" look.

This principle influences the material selection step of the design process. Functionality (i.e., good performance) and cost are no longer the most important selection criteria because they may lead to a combination of incompatible materials. Instead compatibility considerations dominate. The flexibility of blend technology allows the creation of materials that satisfy compatibility and use criteria. It is conceivable that concessions may be made regarding functionality, i.e., although not all requirements are met, certain materials are chosen to give the cheapest module costs.

Recycling materials after their life cycle involves several steps [118]: dismantling, transportation of parts to general assembly, cleaning, processing of reground material into an application. The most important issues are identification of the numerous blends in similar applications, definition of separation procedures in which contaminants are removed, and facile disassembly steps during designing. Costs involved with collection, separation, cleaning, and reprocessing materials mean that this is only a viable concept for blends of engineering plastics with their high property level and high profit margin.

The cascade model (GE Plastics) envisages a cycle of applications for a material in keeping with the deterioration of mechanical and other properties.

Developments are under way to compatibilize the coatings, paints, and other materials used for aesthetic purposes with the main component.

Examples of cascade models for thermoplastics employed by Opel combine PP from battery cases and bumpers to make new fender liners, bumper carriers, and air-filter housings, and convert PC – PBT from old painted bumpers into new spoiler supports [119].

6.2. New Developments

Several promising new developments can be mentioned. PPE – PS blends are used to make expandable beads, which give strong low-density (down to 20 g/dm^3) foams with a heat distortion temperature $> 100\,^{\circ}$C, i.e., a sterilizable, re-usable material [120].

The use of PPE as an organic, heat-resistant, flame-retardant filter that does not affect mechanical properties at high filling ratios has been demonstrated for PA – PPE blends, and can be applied to other blend systems. These new blends include a PPE – PBT blend under development (trade name Gemax, GE Plastics), which has an even lower moisture absorption and thus higher dimensional stability than PA – PPE [121]. The material is targeted for automotive and appliance markets. Blends of chemically modified PPEs will also find increasing use.

Hybrid systems are related blends and consist of thermoset networks filled with heat-resistant engineering thermoplastics [122]. High-performance thermoset materials are used in structural applications where dimensional stability is of the utmost importance. Their temperature stability is determined by the glass transition temperature, whereas their mechanical stability above this temperature is controlled by the network density. Stiffer, more heat-resistant materials can be obtained by using stiffer building blocks or increasing the network density. However, this also increases the brittleness.

Figure 20. Generalized scheme illustrating the importance of resin compatibility in recycling

Incorporation of heat-resistant engineering thermoplastics improves impact behavior while maintaining dimensional stability at high temperatures. Dissolution of these resins in epoxy systems allows easy processing. The thermodynamically controlled phase separation that takes place during the curing of the epoxy resin leads to a high flexibility in controlling the ultimate network density and thus mechanical properties. Commercially available materials include PEI – epoxy systems (Brochier, France) [123–125] intended for metal-laminating structures in the aircraft industry, and PPE – epoxy systems (General Electric, USA) [126], [127]. The latter systems provides another solution to the poor melt processibility of PPE (Section 4.5); it combines the low viscosity and easy processibility of thermosets with the toughness of thermoplastics. A commercial product (Getek, GE Electromaterials) is used as a circuit board material, the presence of PPE allows compliance with highly demanding techniques used for surface mounting and impedance control. A commercially available PPE has been functionalized with head and tail groups to provide optimal adhesion between the PPE phase and final cured epoxy resin. The PPE volume fraction determines whether the product is an epoxy-filled PPE matrix or a con-

tinuous epoxy matrix with a highly dispersed PPE phase.

A new reactive polymer system is based on oxazolines. Copolymers of styrene with a functional oxazoline monomer can react with carboxyl-, amino-, or anhydride-functional polymers to produce graft copolymers [128]. This reactive PS has been used to compatibilize the combination of PPE and an ethylene – acrylic acid copolymer, producing a high-impact engineering blend with excellent strength and processing properties.

Also new are blends of thermoplastics with 5 – 25 % liquid crystalline polymers. The resulting "molecular composite" can be regarded as a material in which the rigid crystalline polymers are reinforced at a molecular level. Liquid crystalline polymer blends have been reported for PC [129], [130]; PEI [129]; PP [131]; PBT [132]; PPE – PS [133]; ABS [134]; PSU [135]; PETP [136], [137]; and PA 6 [138]. These blends can be processed by conventional techniques such as extrusion, injection molding, and fiber spinning. Nearly all combinations of liquid crystalline polymers lead to an immiscible polymer blend. Consequently the mechanical properties of the blends are determined by the morphology of the liquid crystalline polymer domains in the thermoplastics. This morphology depends on composition, processing conditions, viscosity ratio of the component polymers, and the rheological characteristics.

Efforts are being made to use more biodegradable plastics for packaging. Commercial blends of PE with starch have been introduced by Feruzzi. The biodegradability of blends of polycaprolactone and LDPE or PP with cornstarch has been reported [139].

The development of thermoplastic blends for high-temperature composites (at $> 200\,^{\circ}\mathrm{C}$) to be used in structural applications is described in [140]. Polymers with high temperature stability tend to be intractable or brittle, whereas easily processible polymers usually fall short of the projected temperature requirement. Luckily, many high-temperature, aromatic and heterocyclic polymers form miscible blends with each other which permits balancing of thermal response and processibility. Poly(2,2′-metaphenylene-5,5′-bibenzimidazole) (PBI), for example, is miscible with PEI and with PAr; PEI is miscible with PEEK and PEKK.

Blending is also applied to improve the processibility of conductive polymers. Examples are Versicon (Zipperling) intended for transparent electrostatic coatings and corrosion prevention; electrically conductive blend or polyaniline and PVC with EMI properties; and conductive blends of poly(*p*-phenylene vinylene) and polyacrylamide [141]. Blends of (conductive) polyaniline in a matrix of elongated/stretched ultrahigh molecular mass PE are being commercialized by Neste.

6.3. Outlook

Blend technology will accelerate penetration of thermoplastics in markets where its presence is still limited [142]. Designers will have to be made aware of the advantages of working with thermoplastics instead of conventional materials such as wood and metal: their superior performance in a large number of applications, their versatile property profiles, the design freedom, and recycle options. The construction industry is an area with enormous potential for thermoplastic blends and composites. Short-term growth will be driven by applications such as windows, electrical systems, and skylights, followed by the replacement of wood, steel, and concrete. Advantages are lighter constructions, labor savings, and low maintenance costs. A number of possibilities are demonstrated in GE Plastics "Living Environment" concept house and a similar principle developed by Neste. They show the possibilities of thermoplastics and their blends, as well as the use of recycle materials in novel design concepts.

A breakthrough in the automotive market would be large exterior parts and structural components [143]. Two factors limit the use of thermoplastics in body panels. Firstly, cars will continue to feature steel – plastic body construction throughout the 1990s, requiring plastics to withstand vehicle assembly processes designed for steel. Secondly, car makers must compare the overall cost of plastics to steel including tooling, assembly, and customer value rather than on a raw material basis.

Miniaturization is the main driving force for the electronics expanded use of synthetic poly-

mers in the electronics industry. With the development of new molding techniques for high-temperature resins such as polyarylsulfones and poly(phenyletheretherketone), new applications can be realized.

List of symbols

A chemical species; vacant adsorption site
[A] concentration of species A
$[A]_0$ initial concentration of species A
A_1, A_2, A_3 adjustable parameters
ABS acrylonitrile – butadiene – styrene rubber-modified copolymer
ACA aminocaproic acid
$A(h)$ energy required to separate to a distance $h=\infty$, two drops of diameter $d=1$ initially separated by a distance h_0
A_m surface area of micelles
A_p surface area of polymer particles
B chemical species
BHET bis-hydroxyethyl terephthalate
BR batch reactor
C_{pi} dimensionless moments of polymer distribution for chain transfer to polymer $[= K_{fp} Q_i/(K_p[M])]$
C_S surfactant concentration
CCD chemical composition distribution
CMC critical micelle concentration
CPFR continuous plug flow reactor
CSTR continuous stirred-tank reactor with an ideal residence-time distribution
CTA chain-transfer agent
d particle diameter
$\bar{d}$ average particle diameter
d_{32} Sauter mean diameter of a spherical-particle suspension
d_{50} diameter at which 50 wt % of particles pass through a sieve
d_{min} minimum particle diameter
d_{max} maximum particle diameter
D stirrer diameter
D_{op} mean diffusion coefficient for oligomeric radicals and latex particles
DMT dimethyl terephthalate
E_d activation energy for initiator decomposition
E/E_0 mass fraction of material passing out of reactor with a residence time t to $t + dt$
E_f activation energy for chain-transfer reaction
E_L activation energy for average chain lengths
E_N activation energy for polymer particle nucleation
E_p activation energy for propagation
E_R activation energy for polymerization
$E(t)$ residence-time distribution for a flow reactor at steady state
E_t activation energy for bimolecular termination
Eu modified power number
EG ethylene glycol
EGDMA ethylene glycol dimethacrylate
EPS expandable polystyrene
ESR electron spin resonance spectroscopy
f initiator efficiency; functionality of monomer
f_j mole fraction of monomer of type j
$F_{i,in}$ molar flow rate of monomer of type i into the reactor
F_{in} total molar flow rate (of all monomer types) into the reactor
$F_{Ii,in}$ molar flow rate of initiator of type i into the reactor
F_j mole fraction of monomer of type j, chemically bound in polymer produced instantaneously

$\bar{F}_j$ mole fraction of monomer of type j chemically bound in accumulated polymer
$\bar{F}_1$ mole fraction of monomer 1 (containing an abstractable atom) in accumulated polymer
$\bar{F}_2$ mole fraction of monomer 2 (containing a reactive carbon – carbon bond
$F_{\mathrm{p}i,\mathrm{in}}$ molar flow rate of monomer of type i chemically bound in polymer into the reactor
Fr Froude number
$F_{\mathrm{T,in}}$ molar flow rate of chain-transfer agent T into the reactor
G^+ counterion
GPC gel permeation chromatography
HCSTR homogeneous CSTR
HDPE high-density polyethylene
H – H Hui – Hamielec styrene polymerization model
HIPS high-impact polystyrene
I initiator or catalyst
[I] concentration of initiator or catalyst
K chemical rate constant; equilibrium constant
K_{a} absorption constant for oligomeric radicals entering polymer particles
K_{A} adsorption rate constant
K_{d} initiator decomposition constant
K_{dp} depropagation constant
K_{D} desorption rate constant
$K_{\mathrm{f}\,{}^{j}_{i}}$ rate constant for polymeric radical of type i abstracting an atom from monomer of type j chemically bound in polymer
K_{fm} transfer to monomer rate constant
K_{fp} rate constant for chain transfer to polymer
K_{fT} rate constant for chain transfer to CTA
K_{fT^i} rate constant for chain transfer from polymeric radical of type i to CTA
K_{fX} transfer to small molecule X rate constant
K_{i} rate constant for monomer adding to a primary radical
K_{p} propagation rate constant
K'_{p} propagation rate constant for transfer radical
K^-_{p} propagation rate constant for free ion
$K^{\pm}_{\mathrm{p}}$ propagation rate constant for ion pair
$K_{\mathrm{p}*}$ rate constant for polymeric radicals adding to pendant double bonds on polymer chains
$K_{\mathrm{p}\,{}^{j}_{i}}, K_{ij}$ propagation rate constant for monomer of type j adding to polymeric active center of type i
$K_{\mathrm{p}_{ij}}$ rate constant for polymeric radical of type i adding to a double bond on a monomer unit of type j chemically bound in the polymer
$K_{\mathrm{p}_{ijk}}$ propagation rate constant for monomer of type k adding to a polymeric active center of type ij
K_{t} total bimolecular termination constant $(K_{\mathrm{tc}} + K_{\mathrm{td}})$
K_{t0} total bimolecular termination constant at zero conversion of monomer
K_{tc} rate constant for bimolecular termination by combination
$K_{\mathrm{tc}_{ij}}$ termination by combination rate constant for polymeric radicals of types i and j (chemical control)
$\bar{K}_{\mathrm{tcN}}$ number-average bimolecular termination constant by combination
K_{td} rate constant for bimolecular termination by disproportionation
$K_{\mathrm{td}_{ij}}$ termination by disproportionation rate constant for polymeric radicals of types i and j (chemical control)
$\bar{K}_{\mathrm{tdN}}$ number-average bimolecular termination constant by disproportionation
$\bar{K}_{\mathrm{tN}}$ total number-average bimolecular termination constant
K_{tp} termination rate constant in polymer particles
$K_{\mathrm{t}}(r, s)$ total bivariate distribution for diffusion-controlled bimolecular termination of polymeric species of chain lengths r and s
K_{tw} termination rate constant in aqueous phase
$\bar{K}_{\mathrm{tW}}, \bar{K}_{\mathrm{t}Z}$ total weight- and z-average bimolecular termination constants
L characteristic length of energy-containing large eddies
L length of path traversed by a growing radical from its point of origin to the point where it precipitates
L reactor length
LALLS low-angle laser light scattering
LCB long-chain branching

LDPE low-density polyethylene
LLDPE linear low-density polyethylene
m_i number of moles of monomer i in terpolymer (Eq. 3.101)
M_c average molecular mass between cross-links
M_i monomer of type i
M_m aggregation number for emulsifier molecules in micelles
M_{mi} molecular mass of monomer of type i
$\bar{M}_N, \bar{M}_W, \bar{M}_Z, \bar{M}_{Z+1}$ number-, weight-, Z and $Z+1$-average molar mass (molecular mass, respectively)
[M] total monomer concentration
$[M]_0$ initial monomer concentration; monomer concentration in feed
$[M]_c$ equilibrium concentration of monomer at the ceiling temperature
$[M_i]$ concentration of monomer of type i
$[M]_p$ concentration of monomer in the polymer particles
M – H Marten – Hamielec polymerization model
MMA methyl methacrylate
MWD molecular mass distribution (molar mass distribution)
n number of monomer types
n order of reaction
$\bar{n}$ average number of radicals per particle
N_0, N number of functional groups at time zero and t
N total number of moles in the reactor; stirrer speed
N_A number of moles of A-functional groups; Avogadro number
N_{A_0} initial number of moles of A-functional groups
N_B number of moles of B-functional groups
N_{B_0} initial number of moles of B-functional groups
N_i moles of monomer of type i in the reactor
N_I number of moles of initiator in the reactor; number of growing chains
N_{I0} initial number of moles of initiator in the reactor
N_{Ii} moles of initiator of type i in the reactor
$N(r)$ number chain length distribution (number-fraction of polymer molecules of chain length r)
N_M number of monomer units; number of micelles; number of monomer molecules consumed
N_n number of polymer particles containing n radicals
N_p number of polymer particles per unit volume
N_T moles of CTA in reactor
NBR nitrile – butadiene rubber
NIRS near infrared spectroscopy
p conversion of functional groups
p_c critical threshold
P growing polymer particle; polymer
P_c conversion of functional groups at gelation point
P_{cr} critical chain length for precipitation
P_i moles of monomer of type i chemically bound in polymer in the reactor
P_{ij} polymer containing i units of monomer of type 1 and j units of monomer of type 2
$[P_m]$ concentration of polymer with chain length m
$P_{m,n}$ dead polymer chain containing m units of monomer 1 and n units of monomer 2
P_N number-average chain length of polymer produced instantaneously
$\bar{P}_N$ number-average chain length of accumulated polymer
$\bar{P}_N^{sol}$ number-average chain length of sol molecules
P_r polymer molecule of chain length r
P_W weight-average chain length of polymer produced instantaneously
$\bar{P}_W$ weight-average chain length of accumulated polymer
$\bar{P}_W^{sol}$ weight-average chain length of sol molecules
PDI polydispersity index of polymer produced instantaneously
$\overline{PDI}$ polydispersity index of accumulated polymer
PE polyethylene
PEK polyetherketone
PES polyethersulfone
PETP poly(ethylene terephthalate)
PFR plug-flow reactor
PMMA poly(methyl methacrylate)
PP polypropylene
PPS poly(phenylene sulfide)
PS polystyrene

PSD particle size distribution
PVAL poly(vinyl alcohol), partially hydrolyzed
PVC poly(vinyl chloride)
$P*$ polymeric active center
$[P*]$ concentration of polymeric active centers (ionic or radical type)
P_i^* polymeric active center with active center located on monomer of type i chemically bound in the polymer chain
P_{ij}^* polymeric active center with active center located on monomer of type j which is adjacent to monomer of type i chemically bound in the polymer chain
$P_{m,n,i}^*$ polymer chain containing m units of monomer 1, n units of monomer 2, with active center on monomer i
Q_i i-th moment of the dead polymer distribution
r polymer chain length
r polymer particle radius
r_{M} micelle radius
r_{p} polymer particle radius
r_1, r_2 reactivity ratios
R gas constant
$R^\bullet$ polymeric radical
$[R^\bullet]$ concentration of polymeric radicals
Re Reynolds number
R_{f} rate of chain transfer
$R_{\mathrm{FP}}(r)$ production rate of polymer molecules with chain length r
R_{i} rate of radical entry into polymer particles
R_{in}^* initiator/catalyst fragment with an active center
$\hat{R}_{\mathrm{in}}^\bullet$ initiator radical with a peroxide end group
$R_{\mathrm{in}}^\bullet$ initiator or primary radical
$[R_{\mathrm{in}}^\bullet]$ concentration of primary radicals
$R_{\mathrm{i,w}}$ radical generation rate in the aqueous phase via initiator decomposition
R_{I} rate of initiation (rate of generation of polymeric radicals with chain length unity via initiation)
RIM reaction injection molding
R_{p} rate of polymerization (monomer consumption rate via propagation reactions)
R_{p_i} consumption rate of monomer of type i via propagation reactions
$R_{\mathrm{p}_{ij}}$ consumption rate of monomer of type j by propagation with polymeric radicals of type i
$R_{\mathrm{p,o}}$ initial polymerization rate
$R_r^\bullet$ polymeric radical of chain length r
$[R_r^\bullet]$ concentration of polymeric radicals of chain length r
R_{t} rate of bimolecular termination
R_{tc} rate of bimolecular termination by combination
R_{td} rate of bimolecular termination by disproportionation
RTD residence time distribution
$[R^\bullet]_w$ concentration of radicals in the aqueous phase
ΔS^0 entropy change of polymerization at the standard state
S surface area of polymer particle
S surfactant
SAN styrene – acrylonitrile copolymer
SBR styrene – butadiene rubber
SCSTR segregated CSTR
SSH stationary-state hypothesis
t time
$t_{1/2}$ half-life of initiator
t_1 polymer particle nucleation time
t_{s} time when polymer particle nucleation ceases
T temperature
T chain-transfer agent
$T^\bullet$ CTA transfer radical
T_{c} ceiling temperature
T_{g} glass transition temperature
TPA terephthalic acid
TREF temperature rise elution fractionation
U MWD nonuniformity index
v volume of polymer particle
v volumetric flow rate into and out of reactor
v_{c} capture rate of radicals by polymer particles
v_{f} flocculation rate of precipitated (primary) polymer particles
V volume of reacting mixture in the reactor
V_0 intial volume of reacting mixture in the reactor
V_{in} total volumetric flow rate into the reactor
V_{out} total volumetric flow rate out of the reactor

V_m specific volume of monomer
V_p specific volume of polymer
V_s volume of solvent in the reactor
$V_{s,in}$ volumetric flow rate of solvent into the reactor
VCM vinyl chloride monomer
We Weber number
$\bar{W}_g$ weight fraction of gel
$W(r)$ weight chain length distribution (weight fraction of polymer of chain length r)
$W(r), W(r,t)$ "instantaneous" weight chain length distribution
$\bar{W}(r), \bar{W}(r,t)$ weight chain length distribution of accumulated polymer
W_1, W_2 weight fractions of homopolymers 1 and 2
x monomer conversion
X small molecule with a labile atom
$X^\bullet$ transfer radical
z exponent indicating dependence of N_p on emulsifier and initiator concentrations
α stoichiometric imbalance
$\Delta\alpha_1, \Delta\alpha_2$ differences between thermal expansion coefficients above and below T_g for homopolymers 1 and 2
β kinetic parameter (dimensionless)
γ kinetic parameter (dimensionless)
$*\gamma_{prec}$ volume fraction of precipitant
δ kinetic parameter (dimensionless)
ε characterizes the radical capture efficiency of latex particles relative to micelles; energy-dissipation rate
$\bar{\varepsilon}$ mean rate of energy dissipation per unit mass
η moles of monomer consumed per active site ($\equiv \bar{P}_N$)
η_c viscosity of continuous phase
η_d viscosity of disperse phase
ϱ_c density of continuous phase
ϱ_d density of disperse phase
ϱ_{el} elastic cross-link density
ϱ_{m_i} density of monomer i
ϱ_p density of polymer
σ standard deviation
σ^2 statistical variance
σ interfacial tension
σ_{SG} interfacial tension between solid and gas
σ_{SM} interfacial tension between solid and monomer
σ_{SW} interfacial tension between solid and water
σ_{WG} interfacial tension between water and gas
σ_{WM} interfacial tension between water and monomer
τ kinetic parameter (dimensionless)
τ mean residence time
φ phase volume ratio
φ, φ' probability of propagation
φ_m volume fraction of monomer
φ_p volume fraction of polymer
$\dot{\varphi}_i$ number fraction of polymeric radicals of type i (terminal model)
φ_i^* number fraction of active or live polymer molecules of type i (radical or ionic, terminal model)
$\dot{\varphi}_{ij}$ number fraction of polymer radicals of type ij (penultimate model)
Φ kinetic parameter (dimensionless)
χ Flory – Huggins polymer – solvent interaction parameter
$\psi(r)$ number fraction of polymeric radicals of chain length r

1. Introduction–Trends in Polymer Reaction Engineering

The worldwide production of synthetic polymers, estimated at ca. 100×10^6 t/a in 1990 [1] and at ca. 170×10^6 t/a in 2000 [957], continues to grow in spite of criticism from environmentalists. Polymer waste has become an urgent topic for industry, providing new and challenging areas of research and development on recycling, reuse, and degradation. The technical principles of polymer reaction engineering will no doubt play a significant role in the solution of some of these problems. With the increase in production volumes of commodity polymers (LLDPE, HDPE, PP, PVC, and PS copolymers), large-reactor technology (suspension PVC) and continuous processes (production of LLDPE in continuous fluidized-bed reactors, e.g., UNIPOL process) are being developed [1], [2]. In the early days of the polymer industry, polymers were specialty materials, produced in batch reactors by using faithfully followed recipes scaled up from the chemist's beaker. The process engineer, although versed in the principles of chem-

ical reaction engineering, had little background in polymer chemistry, polymerization kinetics, and polymer characterization techniques. This has changed dramatically in the last two decades, as evidenced by the rapid growth of the field of polymer reaction engineering within the chemical reaction engineering discipline. Process parameters, such as residence-time distribution, micromixing, and segregated flow, whose influence on productivity and selectivity of small molecule reactions has been studied for many years, appear to be far more important for polymerization reactors in that they influence polymer properties dramatically [1–7].

The development of engineering and specialty polymers with a better balance of properties or with a particular unique property has been growing rapidly. In this regard, it has been found to be often more economic to produce a new polymer from existing commodity polymers rather than to start with a new monomer and produce polymer in the usual manner. Techniques such as polymer alloying and blending are particularly attractive. These and other techniques use chemical modifications of existing polymers by chain scission, long-chain branching, cross-linking and grafting. These chemical modifications are usually carried out with polymer melts in an extruder reactor [1]. This process is often called reactive polymer processing. This is a new and commercially promising area where the principles of polymer reaction engineering could be profitably exploited.

Since 1980, modeling of polymerization reactors has become more comprehensive. Interest has focussed on the prediction of polymer properties (chemical composition and molecular mass distribution, long-chain branching, cross-link density, polymer particle size distribution, and particle morphology). To develop a predictive model, account must be taken of the chemistry and physics of all of the relevant microscopic processes which occur in the polymerization process. Detailed physical property and thermodynamic data on the partitioning of species among phases is required to quantitatively calculate the concentrations of reactants at the loci of polymerization. Valid kinetic rate constants (frequency factors and activation energies) are also required. In this regard, one should note that the values for individual elementary rate constants are often not required. In the models, groups of rate constants often appear when calculating rates and polymer properties. A knowledge of the Arrhenius equation (overall frequency factor and activation energy) is usually sufficient. Another factor which should be noted is that process models, no matter how detailed, cannot track polymerization rates and polymer properties in real time without feedback from online sensors. The variability in trace impurity levels cannot be accounted for without periodically adjusting kinetic parameters in a process model. The great effort made by chemical kineticists to measure individual elementary rate constants are not in vain. Elementary rate constants can be related to the structure of the reactants, but more importantly for process modelers, elementary rate constants can be used to discriminate kinetic models (for example, the terminal and penultimate models in copolymerization). At this point it is appropriate to emphasize the need for on-line sensors to monitor polymer properties so that process models can be used more effectively in state estimation and control.

2. Polymerization Mechanisms and Kinetics

Polymerization reactions can be classified as either step-growth or chain-growth reactions. It has been proposed that these mechanisms should be termed random and sequential polymerizations [18], [19] since these terms have more significance statistically and are devoid of inference concerning the chemistry of the reactions involved in the polymerizations. In this article, however, the conventional terms step-growth and chain-growth polymerization are used. It is important to note that this is a classification of reaction mechanisms, not of the structure of the repeating unit, since many polymers can be synthesized either by step-growth or chain-growth polymerization. Generally, however, polymer physical properties can differ significantly depending on the polymerization mechanism, and this is often due to the difference in molecular masses, i.e., polymers synthesized by chain-growth polymerization often have higher molecular masses.

These two types of growth reaction differ basically in terms of the time-scale of vari-

ous reaction events, namely, the size of polymer molecules increases at a relatively slow rate over a much longer period of time in step-growth polymerization. With step-growth polymerization, the reactions that link monomers, oligomers, and polymers involve the same reaction mechanism, and any two molecular species (monomer, oligomer, or polymer) can be coupled. The growth of a polymer chain proceeds slowly from monomer to dimer, trimer, tetramer, and so on, until full-sized polymer molecules are formed at high monomer conversions. Polymer chains continue to grow from both ends throughout the polymerization and, therefore, both chain lifetimes and polymerization times are usually of the order of hours.

Figure 1. Linear polymers produced via step-growth polymerization

On the other hand, in chain-growth polymerization, polymer molecules generally grow to full size in a time-scale which is much smaller than the time required for high conversion of monomer to polymer. The lifetime of a growing polymer molecule may be less than a few seconds for a free-radical polymerization, which is a typical example of chain-growth polymerization, while a typical polymerization time to obtain high monomer conversion may be several hours. Chain-growth polymerizations require an active center, which may be a free radical, cation, or anion. Once an active center is created, a polymer chain grows extremely rapidly, and when the growing chain is deactivated by a termination reaction, the polymer chain is dead and no longer takes part as a reactant. With free-radical polymerization, however, the so-called dead polymer chain is not always truly dead because under certain circumstances it may itself react with radicals. The active center may initiate the growth of many polymer chains.

Figure 2. Number chain length distribution in linear step-growth polymerization

2.1. Step-Growth Polymerization

2.1.1. Linear Polymerization

Figure 1 shows some representative linear polymer chains produced commercially by step-growth polymerization. In step-growth polymerization, there is generally only one type of chemical reaction which links molecules of all sizes. Some of the typical chemical reactions are esterification, amidation, the formation of urethanes, and aromatic substitution. The growth reaction in step-growth polymerization can be represented by the general reaction

$$m\,\text{mer} + n\,\text{mer} \longrightarrow (m+n)\,\text{mer} \tag{2.1}$$

The kinetic study of such reactions would be extremely difficult if the rate constant for the coupling reaction depended on the size of both species. Fortunately, various kinetic studies have shown that the rate constant is effectively independent of chain length except perhaps for oligomers. This is often referred to as the concept of equal reactivity of functional groups.

Consider the example of step-growth polymerization shown below.

$$n\,\mathrm{A-A} + n\,\mathrm{B-B} \rightarrow \left[\mathrm{A-A-B-B}\right]_n \tag{2.2}$$

In the case of polyesterification of a diol and a diacid, A may be a hydroxyl group and B may be a carboxyl group, although the low molecular mass condensation byproduct is not shown. As will be shown later, an almost exact equivalence in the number of functional groups is necessary to obtain polymers with high molecular mass, although a nonstoichiometric condition may be used to control molecular mass. In the case of exact stoichiometric ratio of the two types of functional groups, i.e., [A] = [B], the polymerization rate or the rate of disappearance of functional groups is given by

$$-\frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{A}])}{\mathrm{d}t} = K\,[\mathrm{A}]^2 \tag{2.3}$$

except for self-catalyzed polymerization, in which case the rate is third order in monomer (the self-catalyzed polymerization may not be a useful reaction from the practical point of view of productivity). Neglecting the volume change during polymerization, integration of Equation (2.3) gives

$$1/\,(1-p) = 1 + K\,[\mathrm{A}]_0\,t \tag{2.4}$$

where $[\mathrm{A}]_0$ is the initial (at $t = 0$) concentration of A groups, and p is the conversion of functional groups, which is defined as

$$p = \left(N_{\mathrm{A}_0} - N_{\mathrm{A}}\right)/N_{\mathrm{A}_0} \tag{2.5}$$

where N_{A_0} and N_{A} are the total number of moles of A groups at $t = 0$ and at any later time t, respectively. Equation (2.4) has been verified by several kinetic studies. As shown here, the rate expression for a step-growth polymerization is the same for monomer molecules, oligomers, and polymers.

The relationship between the average number of structural units (A–A and B–B in the above example), namely, the number-average chain length $\bar{P}_{\mathrm{N}}$ and the conversion of functional groups p for linear step-growth polymerization was first derived by Carothers [20]. $\bar{P}_{\mathrm{N}}$ is simply given as the total number of monomer molecules initially present divided by the total number of molecules present at time t.

$$\bar{P}_{\mathrm{N}} = N_{\mathrm{A}_0}/N_{\mathrm{A}} = 1/\,(1-p) \tag{2.6}$$

Figure 3. Weight chain distribution in linear step-growth polymerization

Equation (2.6) shows that very high conversions are necessary to obtain large chain lengths. For example, $\bar{P}_{\mathrm{N}} = 100$ requires a conversion of 99 %. Equation (2.6) assumes a stoichiometric ratio of unity. If a slight excess of one bifunctional monomer is used, all chain ends will eventually consist of the group present in excess. When $N_{\mathrm{A}_0} < N_{\mathrm{B}_0}$, the stoichiometric imbalance α is given by $\alpha = N_{\mathrm{A}_0}/N_{\mathrm{B}_0}$. The total number of monomer molecules initially present is given by $(N_{\mathrm{A}_0} + N_{\mathrm{B}_0})/2 = N_{\mathrm{A}_0}\,(1 + 1/\alpha)/2$. Now consider the situation at conversion p (p is usually defined with respect to the deficient group, so that p is defined for A groups in this example). Since each chain end is an unreacted functional group, the total number of end groups is $[N_{\mathrm{A}_0}\,(1-p) + N_{\mathrm{B}_0}\,(1-\alpha p)]$. Each molecule possesses two end groups, so that the total number of polymer (plus monomer) molecules is $[N_{\mathrm{A}_0}\,(1-p) + N_{\mathrm{B}_0}\,(1-\alpha p)]/2$. Therefore, Equation (2.6) can be modified as follows

$$\bar{P}_{\mathrm{N}} = \frac{N_{\mathrm{A}_0}\,(1 + 1/\alpha)\,/2}{\left\{N_{\mathrm{A}_0}\,(1-p) + N_{\mathrm{B}_0}\,(1-\alpha p)\right\}/2} = \frac{1+\alpha}{1+\alpha-2\alpha p} \tag{2.7}$$

As conversion p approaches unity, $\bar{P}_N$ approaches $(1+\alpha)/(1-\alpha)$. Thus if $\alpha = 0.99$, the maximum number-average chain length is only 199. This example illustrates the importance of precise control of the stoichiometric ratio to obtain a desired chain length.

In general, in order to produce high molecular mass polymer by step-growth polymerization, the system must satisfy the following requirements:

1) Very accurate control of the stoichiometric ratio of functional groups
2) Absence of side reactions
3) Availability of high-purity monomers
4) Reasonably high polymerization rate
5) Little tendency towards cyclization reactions

Figure 4. Nonlinear (network) polymers produced via step-growth polymerization

Since high molecular mass polymer is not produced until nearly complete conversion of monomer has occurred, the viscosity is relatively low throughout most of the conversion range. Thermal control and mixing is not overly difficult, which is opposite to the case for chain-growth polymerization. These are some of the reasons why bulk polymerization is quite often used commercially for the production of polyesters and polyamides.

The molecular mass distribution can most easily be derived by using statistical methods for a stoichiometric ratio of unity [21]. The conversion p can be interpreted as the probability that a functional group selected at random has reacted. Consider the probability that a randomly selected molecule consists of r monomer units (this quantity is equal to the number chain length distribution). This polymer molecule possesses $r-1$ reacted functional groups, and one unreacted functional group. Therefore, the number chain length distribution, $N(r)$ is given by

$$N(r) = p^{(r-1)}(1-p) \tag{2.8}$$

The weight chain length distribution $W(r)$ is given by

$$W(r) = r\,N(r) \Big/ \sum_{r=1}^{\infty} r\,N(r) = r\,p^{(r-1)}(1-p)^2 \tag{2.9}$$

The number and weight chain length distributions are shown schematically in Figures 2 and 3, respectively. The weight-average chain length is given by

$$\bar{P}_W = \sum_{r=1}^{\infty} r\,W(r) = (1+p)/(1-p) \tag{2.10}$$

Since the number-average chain length is given by Equation (2.6), the polydispersity index, $\overline{\mathrm{PDI}} = \bar{P}_W/\bar{P}_N$, is given by $(1+p)$, and therefore the $\overline{\mathrm{PDI}}$ approaches two as complete conversion is approached.

Various statistical treatments other than that shown above have been developed to calculate the molecular mass distribution for linear step-growth polymerization [22–26]. Although these statistical methods appear to work well, kinetic approaches based on the use of material balances may have greater generality [27–33]. For an A–B type monomer in a batch reactor, Equations (2.8) and (2.9) can also be derived from the following infinite set of differential equations.

$$\mathrm{d}\,[\mathrm{P}_1]/\mathrm{d}t = -2K\,[\mathrm{P}_1]\,[\mathrm{P}] \tag{2.11}$$

$$\mathrm{d}\,[P_m]/\mathrm{d}t = K \sum_{r=1}^{m-1} [\mathrm{P}_r]\,[\mathrm{P}_{m-r}] - 2K\,[\mathrm{P}_m]\,[\mathrm{P}] \quad (m \geq 2) \tag{2.12}$$

where $[P_m]$ is the concentration of polymer molecules with chain length m, and [P] is the total concentration of polymer and monomer.

For example, it is straightforward to derive the molecular mass distribution for the cases in which a slight amount of monofunctional reagent is used. Kinetic approaches would be easier to apply to reactors other than batch reactors, such as semi-batch and continuous flow reactors, although a statistical derivation for a stirred-tank reactor has been reported [34].

2.1.2. Interfacial Polymerization

Interfacial polymerization may provide a method to produce very high molecular mass polymers by step-growth polymerization [35], [36]. In interfacial polymerization, polymers are formed at or in the vicinity of the phase boundary of two immiscible monomer solutions. This technique requires an extremely fast polymerization. The best reaction type for step-growth polymerization would be Schotten – Baumann reactions involving acid chlorides. For example, polyamidation is performed at room temperature by placing an aqueous solution of diamine over an organic phase containing the diacid chloride. The polymer formed at the interface can be pulled off as a continuous film or filament. The amine – acid chloride reaction rate is so fast that the polymerization becomes diffusion controlled. Once the polymer molecules begin to grow and monomer molecules start to add to polymer chain ends, incoming monomer molecules tend to react with polymer chain ends before they can penetrate through the polymer film to start the growth of new chains. Thus, polymers with much higher molecular masses are formed. Since the reaction is diffusion controlled, there is no need to start with an exact balance of the two monomers. The lower temperatures used reduce the relative rates of side reactions, and, therefore, the purity of monomers is not as important as with most other step-growth polymerizations. In spite of the advantages that interfacial polymerization offers, this process has not attracted wide industrial use, mainly because of the high cost of the required reactive monomers and the large amount of solvent which must be removed and recovered.

2.1.3. Nonlinear Polymerization

Another important class of polymers produced by step-growth polymerization are nonlinear polymers formed by polymerization of monomers with more than two functional groups per molecule. Some of the nonlinear polymers produced commercially by step-growth polymerization are shown in Figure 4.

In the course of network formation, a polymer molecule of effectively infinite molecular mass may be formed. At this point, termed the gel point, the visible formation of a gel or insoluble polymer fraction is observed. The gel molecule is insoluble in a good solvent even at elevated temperatures under conditions at which degradation does not occur. Various physical properties of the system change abruptly at the gel point. Gelation should be understood as a critical phenomenon having similarities with other critical phenomena such as vapor – liquid condensation, nuclear chain reactions, and ferromagnetism.

It was Carothers [20], who first derived an equation for the extent of reaction at the gel point. He defined a gel molecule as one with infinite molecular mass. His criterion that gelation occurs when the number-average chain length $\bar{P}_N$ goes to infinity is not acceptable, since polymer molecules larger than $\bar{P}_N$ are always present and will become gel molecules earlier than this hypothetical gel point. However, the concept of the "infinitely large molecule" was fully established by Flory [37–39] using a statistical approach. His criterion for the onset of gelation is that it occurs when the weight-average chain length $\bar{P}_W$ goes to infinity. Since a gel molecule is the largest molecule in the reaction system, higher-order moments of the molecular mass distribution could also be used to determine the gel point. Fortunately, the second- and higher-order moments approach infinity simultaneously, at least for batch polymerizations [40], [41], and the criterion of infinite $\bar{P}_W$ is acceptable.

Flory devised a simple tree-like model, as shown in Figure 5, and used the following simplifying assumptions:

1) All functional groups of the same type are equally reactive
2) All functional groups react independently of one another

3) No intramolecular reactions occur in finite species

Figure 5. A schematic drawing of Flory's tree-like model (functionality $f = 3$)
The tree-like model is called the Bethe Lattice or Cayley tree by physicists

Figure 6. Molecular mass change and gel growth during network formation (functionality $f = 3$)

His basic proposal was that the gel point is reached when the expectancy of finding the next generation in a particular existing molecule is unity. For the tri-functional monomer units shown in Figure 5, the conversion at the gel point is given by $p_c = 1/(f - 1) = 0.5$, where f is the functionality of a monomer unit. His model was a brilliant development and it provides the starting point for most theories of polymer network formation. A few years later Stockmayer [42–44] further developed Flory's idea based on the most-probable size distribution, and their theory is usually called the Flory – Stockmayer theory. Examples of the calculated development of the number- and weight-average chain lengths of the sol fraction and of the weight fraction of gel are shown in Figure 6. Since the gel is a molecule with many functional groups, the gel once formed acts like a giant sponge, rapidly consuming sol polymer molecules.

This tree-like concept was generalized by Gordon et al. [45], [46] based on the theory of stochastic branching processes, which is considered to be a part of Graph Theory [47], [48]. This technique involves abstract mathematics and requires the derivation of the probability generating functions. The method is general but rather difficult to use for real problems. To avoid the use of probability generating functions, other probabilistic methods have been proposed [49–52]. Among them the Macosko – Miller model [50–52] using conditional probabilities is becoming popular due to its simplicity. All the models mentioned above are fully equivalent, that is, only the mathematical language is slightly different. These statistical models, which are sometimes called the classical theories, have a long history and have proven their power of refinability to accommodate highly system-specific effects such as unequal reactivity [53], [54], substitution effects [55], [56], and intramolecular reactions [18], [19], [57–59], which are important in real systems.

One drawback of the statistical theories mentioned above is that they assume an equilibrium system (i.e., the size distribution is calculated anew at each time) and they do not consider the kinetic buildup of the system. Therefore, the classical theories may not be applicable for kinetically-controlled systems. It has been shown that although there is no difference between equilibrium and kinetically-controlled systems under Flory's simplifying assumptions, the difference becomes significant as the conditions deviate further from Flory's assumptions [60], [61], so that in real systems the kinetic features may be dominant. It has been argued that the kinetic buildup can also be accounted for by using a statistical approach [62].

Another disadvantage of statistical approaches may be the excessive modifications required to generalize them for different reactor types (e.g., continuous reactors). The kinetics approach was originally shown in the appendix of a paper by Stockmayer [42]. Based on the chemical kinetics, the reaction rate would be proportional to the product of the number of unreacted functional groups in the respective reaction partner, so that an infinite set of differential

equations similar to Equations (2.11) and (2.12) can be set up. This idea has been applied to polymeric systems [60], [63–70].

Figure 7. Example of percolation at the gel point in a square lattice ($p_c = 0.5$) [78]

All the theories mentioned above belong to a mean-field theory. On the other hand, the percolation theory [71–77], which is considered to be equivalent to a non-mean-field theory, has been applied to polymeric gelation [78], [79]. The percolation theory is usually associated with a lattice model to describe network structure. One of the simplest examples is the two-dimensional lattice shown in Figure 7. In this figure, each bond which has been formed is shown as a short line connecting two monomers, though the monomers are not shown. In the random (standard) percolation theory each site of a very large lattice is occupied randomly with probability p, independent of its neighbors. Some nearly "infinite" molecules can be seen in Figure 7, where "infinite" means that they span the whole sample. Mathematical methods to calculate this threshold exactly are restricted so far to two dimensions [77], and therefore, for practical calculations the Monte Carlo simulation is usually used. It is easy to understand why gelation is a critical phenomenon from the lattice model, because in the vicinity of the gel point only a few additional bonds are necessary to form a molecule which spans the whole sample. The percolation theory emphasizes the universality of critical phenomena and space dimensionality. De Gennes wrote in his book [80] that "it took more than thirty years to convince experimentalists that mean-field theory was wrong". However, at present the percolation models are far from simulating actual network formation quantitatively, because the bonds are too rigid, the movement of molecules is too suppressed, and necessary chemical rules of bond formation are ignored. The percolation theory is essentially devoted to describing the behavior near the critical threshold p_{cr}, where the system-specific features are not important.

Network polymers are increasingly used as engineering materials because of their excellent stability toward elevated temperature and physical stress. Since the three-dimensional polymers are neither soluble nor fusible once made, the final stage of polymerization is usually carried out in a mold of the desired shape.

2.2. Chain-Growth Polymerization

Chain-growth polymerization is initiated by a reactive species, R^*_{in}, produced from an initiator or catalyst I.

$$I \longrightarrow n\,R^*_{in} \tag{2.13}$$

Depending on the type of active center, chain-growth polymerization can be divided into free-radical, anionic, and cationic polymerization. The reactive species R^*_{in} adds to a monomer to form a new active center, and monomer molecules are added to the active center successively. This process is called the propagation reaction:

$$R^*_{in} \xrightarrow{+M} P^*_1 \xrightarrow{+M} P^*_2 \xrightarrow{+M} \cdots \tag{2.14}$$

where M represents a monomer molecule, and $P*_r$ is an active polymer molecule with chain length r. In general, the propagation reaction is represented by

$$P^*_r + M \xrightarrow{K_p} P^*_{r+1} \tag{2.15}$$

In chain-growth polymerization, only molecules with an active center can propagate, so that polymer molecules once formed may be considered dead polymer for linear chain-growth polymerization. Dead polymer

molecules do not take part as reactants thereafter. The active center is always on the chain end when linear chains are being produced exclusively. Polymer chain growth is terminated at some point by unimolecular and/or bimolecular termination. Bimolecular termination of active centers occurs only in free-radical polymerization.

Carbon – carbon double bonds and the carbon – oxygen double bond in aldehydes and ketones are the two main types of functional groups which undergo chain-growth polymerization. The polymerization of the carbon – carbon double bond is much more important, as most commercial monomers with carbon – carbon double bonds readily undergo free-radical polymerization (an important exception is propene). The carbonyl bond is not generally susceptible to polymerization by radical initiators due to its highly polarized structure. Another reason is that most of the carbonyl monomers (except formaldehyde) possess very low ceiling temperatures [81], [82] (the temperature above which active polymer chains depolymerize rather than grow).

Most of the commercial vinyl monomers (CH_2=CHX and CH_2=CXY, and monomers in which fluorine is substituted for hydrogen) can be polymerized with free radicals. Whether a vinyl monomer can be polymerized by anionic or cationic mechanisms strongly depends on the type of monomer. Monomers with electron-donating groups attached to the doubly bonded carbon atoms form stable carbenium ions and polymerize best with cationic initiators. Conversely, monomers with electron-withdrawing substituents form stable carbanions and require anionic initiators. It should be noted that ions of low stability would be expected to react with carbon – carbon double bonds; however, in many cases they cannot be formed or else are easily consumed by side reactions.

2.2.1. Free-Radical Polymerization

Generally, free-radical polymerization consists of four types of elementary reaction.

1) Initiation reactions, which continuously generate radicals during polymerization.

$$\mathrm{I} \xrightarrow{K_d} n\,\mathrm{R}^{\bullet}_{in} \tag{2.16}$$

$$\mathrm{R}^{\bullet}_{in} + \mathrm{M} \xrightarrow{K_i} \mathrm{R}^{\bullet}_{1} \tag{2.17}$$

The stoichiometric coefficient n is two for thermal decomposition of initiators. A free-radical $\mathrm{R}^{\bullet}_{in}$ derived from the initiator is called a primary or initiator radical.

2) Propagation reactions, which are responsible for the growth of polymer chains by addition of monomer to a radical center.

$$\mathrm{R}^{\bullet}_{r} + \mathrm{M} \xrightarrow{K_p} \mathrm{R}^{\bullet}_{r+1} \tag{2.18}$$

3) Bimolecular termination reactions between two radical centers, which give a net consumption of radicals. These consist of disproportionation (Eq. 2.19) and combination (Eq. 2.20).

$$\mathrm{R}^{\bullet}_{r} + \mathrm{R}^{\bullet}_{s} \xrightarrow{K_{td}} \mathrm{P}_{r} + \mathrm{P}_{s} \tag{2.19}$$

$$\mathrm{R}^{\bullet}_{r} + \mathrm{R}^{\bullet}_{s} \xrightarrow{K_{tc}} \mathrm{P}_{r+s} \tag{2.20}$$

where P_r is a polymer molecule of chain length r and does not have a radical center, while a polymer radical (or macroradical) of chain length r has the symbol $\mathrm{R}^{\bullet}_{r}$.

4) Chain transfer to small molecules which causes the cessation of growth of polymer radicals while generating small transfer radicals simultaneously. Chain-transfer reactions do not give a net consumption of radicals, and if the transfer radicals are as reactive as polymer radical (or more reactive) these reactions should not affect the polymerization rate or monomer consumption rate when the bimolecular termination reactions are chemically controlled. Chain-transfer reactions to small molecules reduce the size of polymer radicals and therefore would increase bimolecular termination rates when these reactions are diffusion controlled (bimolecular termination rates may be chain-length dependent under these conditions).

$$R_r^{\bullet} + X \xrightarrow{K_{rx}} P_r + X^{\bullet} \quad (2.21)$$

$$X^{\bullet} + M \xrightarrow{K_p'} R_1^{\bullet} \quad (2.22)$$

X may be monomer, a solvent molecule, or a chain-transfer agent. When X is a polymer molecule, polymer molecules with long-chain branches are formed. Long-branch formation is discussed in Section 2.2.1.7.

The sequence of elementary reactions, in Equations (2.16) – (2.22) results in total radical concentrations of the order $10^{-9} - 10^{-5}$ mol/L for most commercial polymerizations. Since polymer molecules with high molecular masses are produced from the very start of polymerization, the reacting solution can be quite viscous over most of the monomer conversion range. The high viscosities not only cause problems in mixing and heat removal, but also can affect reaction rates (reactions such as bimolecular termination of polymer radicals). This topic is discussed in Section 2.2.1.3.

Free-radical polymerization is the most commonly used method for the synthesis of polymers from vinyl and divinyl monomers. Some typical monomers which readily undergo free-radical polymerization are ethylene, styrene, vinyl chloride, vinylidene chloride, acrylonitrile, vinyl acetate, methyl methacrylate, methyl acrylate, acrylamide, etc. Of all chain-growth polymerization processes, it is the most widely studied and best understood.

2.2.1.1. Initiation

Free radicals may be generated in a monomer in a number of ways. The most often used method is to add chemical initiators, such as azo and peroxide compounds, to the monomer in low concentrations (usually < 1 wt % based on monomer). When heated, the initiator decomposes, generating radicals which act as active centers for monomer addition. For example, organic peroxides (ROOR′) decompose thermally by O – O bond cleavage to produce two initiator radicals as follows (other side reactions may of course occur).

$$ROOR' \xrightarrow{K_d} RO^{\bullet} + R'O^{\bullet} \quad (2.23)$$

where K_d is a thermal decomposition rate constant with units of inverse time, most often s^{-1}. For a batch reactor, the change in the number of moles of initiator N_I is given by

$$dN_I/dt = -K_d N_I \quad (2.24)$$

For isothermal decomposition (isothermal polymerization) Equation (2.24) can be integrated analytically to obtain

$$N_I = N_{I0} \exp(-K_d t) \quad (2.25)$$

where N_{I0} is the number of moles of initiator at time $t = 0$.

Thus the half-life of an initiator is given by

$$t_{1/2} = -\ln(0.5)/K_d = 0.693/K_d \quad (2.26)$$

Knowledge of K_d for an initiator therefore permits calculation of the initiator half-life $t_{1/2}$. Since K_d has an Arrhenius temperature dependence, K_d and $t_{1/2}$ both depend on temperature.

Activation energies for peroxides and azo initiators are ca. 120 kJ/mol, so the decomposition rate is highly temperature dependent, and the useful temperature range is quite small (decomposition rate is either too fast or too slow outside the useful temperature range, which normally spans about 30 °C).

To complete the initiation step, the initiator radicals ($R_{in}^{\bullet}$) must add to the double bond of a monomer molecule to generate a polymer radical of unit chain length $R_1^{\bullet}$. In most polymerizations, this step (Eq. 2.17) is much faster than the rate of initiator decomposition (Eq. 2.16). The homolysis of the initiator is the rate-determining step in the initiation sequence, and the initiation rate R_I is given by

$$R_I = 2K_d f [I] \quad (2.27)$$

where f is the initiator efficiency. The initiator efficiency is defined as the fraction of radicals produced by initiator decomposition that initiate polymer radicals. Note that not every initiator molecule, which in principle can produce two polymer radicals, does so. Some primary radicals may react with themselves or with other molecules to form stable species which do not form either polymer radicals or molecules. It should be noted that chain transfer to the initiator does not decrease f. The initiator efficiency

usually has values in the range 0.2 – 1.0 at low monomer conversions, where polymer concentrations are low. The major cause of low initiator efficiency is recombination of the radical pairs before they diffuse apart, which is called the cage effect [83], [84]. When an initiator decomposes, the primary radicals $R^{\bullet}_{in}$ are nearest neighbors for about $10^{-10} - 10^{-9}$ s. During this interval they are surrounded by a "cage" of solvent and monomer molecules through which they must diffuse to escape from the cage. Since reactions between radicals are extremely fast, there is reasonable probability that reaction between primary radicals occurs. Direct recombination may simply regenerate the original initiator molecules, but other reactions can also occur that consume initiator radicals without forming polymer chains. In particular, since azo initiators decompose with the elimination of a nitrogen molecule, recombination of the primary radicals results in the formation of a stable molecule that cannot generate radicals, and thus there may be a significant decrease in initiator efficiency. Efficiency decreases with increasing viscosity of the reaction medium [85], [86]. Thus f decreases during the course of polymerization and may approach zero at very high polymer concentrations where the diffusion coefficient of primary radicals in the "cage" is very small [87], [88].

When selecting an initiator type, in general one needs to consider the decomposition rate constant, water and oil solubility, stability of initiator fragments on chain ends, and other factors. Another important point is the activity of the initiator radical center towards the abstraction of atoms (e.g., hydrogen atoms) from the polymer backbone. This can lead to chain scission, long-chain branching, and possibly cross-linking.

Up to this point, only monofunctional initiators (initiators with one peroxide or one azo group per molecule) have been considered. There are commercially available bifunctional initiators (with two peroxide groups per molecule) with some potentially useful applications [89–92]. Their function can be illustrated as follows:

$$\underset{(\mathrm{I})}{R^1OOR^2OOR^1} \longrightarrow \underset{(R^{\bullet}_{in})}{R^1O^{\bullet}} + \underset{(\hat{R}^{\bullet}_{in})}{{}^{\bullet}OR^2OOR^1} \tag{2.28}$$

Even when the K_d's for both peroxide groups are the same, both groups on the same peroxide molecule do not decompose at the same time; thus a significant fraction of the polymer chains will have a peroxide end group. These terminal peroxide groups will later decompose, generating polymer radicals with an initiator fragment in the backbone. The practical benefits include higher molecular masses at the same temperature or comparable molecular masses at higher temperatures. Polymerization at higher temperatures results in higher productivity. These benefits will only accrue when most of the polymer chains are formed by bimolecular termination of polymer radicals. When chain transfer to small molecules produces most of the polymer chains, these benefits will no longer exist, and since bifunctional initiators are more expensive than monofunctional initiators it is recommended that the latter be used.

The decomposition rates of peroxy and azo compounds can be increased by irradiation with ultraviolet and visible light. Unlike thermal decomposition, the activation energy for photochemical initiation is approximately zero, so polymerization can be initiated at much lower temperatures. Compounds such as benzoin and disulfides, whose bonds are too strong to undergo thermal homolysis, are effective radical initiators under ultraviolet irradiation. Photochemical polymerization has been applied in coatings and inks for metal, paper, wood and plastics, in photo-imaging, printing circuits, and adhesives, although its use is limited by low penetration into the polymerizing mass.

Another method of lowering the activation energy of the peroxide decomposition reaction is to use redox initiation systems. The addition of a reducing agent results in radical formation from an oxidation – reduction reaction between the two components. Generally, the reaction is illustrated as follows.

$$A^{n+} + ROOR' \longrightarrow A^{(n+1)+} + R'O^{\bullet} + RO^{-} \tag{2.29}$$

where A is a reducing agent and ROOR′ is a peroxide. The integer n is two for Fe^{2+} and zero for N,N-dimethylaniline. The fate of the free radical depends on the relative concentration of reducing agent and monomer. Since the redox initiaton reactions do not produce a pair of radicals, the cage effect is not operative. At high monomer

concentrations most of the free radicals initiate polymerization, and ordinary second-order kinetics are obeyed. Redox initiation is usually used in the temperature range 0 – 50 °C.

All methods mentioned above employ initiators. There are, however, other means to initiate polymerization. Styrene (and some substituted styrenes such as *p*-methylstyrene) and methyl methacrylate polymerize at elevated temperatures in the absence of a free-radical initiating system. The accepted mechanism for thermal initiation of styrene is the Mayo mechanism [93], [94], which involves the formation of a Diels – Alder dimer intermediate which reacts with styrene to produce radicals. The Mayo mechanism is consistent with an observed initiation rate which can vary from second to third order in monomer during the course of polymerization [95–97], and some confirming evidence has been reported [98–100]. A serious disadvantage of the use of thermal initiation for styrene is the formation of undesirable byproducts (cyclic dimers and trimers) which are difficult to remove to give a high-quality polystyrene.

Irradiation with UV, high-energy electrons, and γ-rays can initiate polymerization with or without the presence of initiators. Radiation initiation has been used almost exclusively for polymer modification (chain scission, long-chain branching, cross-linking, and grafting). These radiation processes are characterized by a zero activation energy for radical generation and as a consequence a low activation energy for polymerization. Therefore, they are effective at both low and high temperatures. With radiation initiation, polymer molecular masses increase with increasing temperature, which is opposite to that for chemically initiated free-radical polymerizations (the high activation energy for initiator decomposition is responsible for this). Both UV and electrons have small penetration depths and are therefore used for polymerizations in thin layers. Gamma rays have high penetration depths but require expensive safety installations. Radiation polymerization may be initiated by radicals, cations, or anions. The effectiveness of a radical center depends on the chemistry of the monomer and the polymerization conditions. Most radiation polymerizations are free-radical except at very low temperatures where ionic species are sufficiently stable. With radiation initiation various active intermediates may be formed, leading to a very complex reaction mixture with the formation of many byproducts as well as the formation of long branches and possibly cross-linkages. Since photon energies for UV are lower, UV radiation generally gives cleaner polymerizations with the formation of linear chains, although monomers which undergo photolysis by UV radiation are limited.

2.2.1.2. Propagation

The propagation reaction (Eq. 2.18) controls both the rate of growth and the structure of the polymer chain. Monomers which undergo free-radical polymerization are commonly monosubstituted or 1,1-disubstituted ethylenes, CH_2=CHX or CH_2=CXY. With 1,1-disubstituted ethylenes both substituents should not be large, since propagation would be sterically hindered. 1,2-Disubstituted ethylenes are normally considered very difficult to polymerize since the approach of the propagating radicals to a monomer is sterically hindered. 1,2-Disubstituted ethylenes can, however, often be incorporated into copolymers.

Due to steric and resonance effects, vinyl monomers predominantly undergo head-to-tail addition:

(2.30)

In certain cases when the substituents are small and do not have large resonance stabilizing effects, head-to-head propagation may occur. For example, approximately 16 % head-to-head placement has been reported for poly(vinyl fluoride) [101].

In free-radical polymerization, chain microstructure is largely independent of initiation mechanism and initiator type. Polymers produced by free-radical polymerization are largely atactic, since the terminal carbon – carbon bond can rotate freely during chain growth. The configuration of a monomer unit in the chain is not determined during its addition to the radical center but only when the next monomer molecule adds to it. The slight preference for syndiotactic over isotactic placement is caused by steric and/or electrical repulsion between

substituents in the chain, although at high temperatures their effects are progressively diminished. For example, the fraction of syndiotactic diads of poly(vinyl chloride) changes from 0.67 to 0.51 as the synthesis temperature increases from − 78 °C to 120 °C [102]. For methyl methacrylate, it is 0.86 at − 40 °C and 0.64 at 250 °C [103], [104].

For most chain-growth polymerizations (free-radical or ionic) the propagation reactions are reversible at elevated temperature and the rate of depropagation is significant [105], [106].

$$R_r^{\bullet} + M \underset{K_{dp}}{\overset{K_p}{\rightleftharpoons}} R^{\bullet}_{r+1} \tag{2.31}$$

where K_{dp} is the rate constant for depolymerization (depropagation). The ceiling temperature T_c, which is the temperature above which active polymer chains depolymerize rather than grow, is reached when the propagation and depropagation rates are equal. Based on thermodynamic arguments, the ceiling temperature can be related to the equilibrium monomer concentration $[M]_c$ as follows:

$$T_c = \Delta H / \left(\Delta S^0 + R \ln [M]_c\right) \tag{2.32}$$

where ΔH is the heat of polymerization, ΔS^0 the entropy change of polymerization at unit monomer concentration, and R the gas constant.

The ceiling temperature T_c is not a singular value but is a function of monomer concentration. At any temperature, a concentration of monomer exists at which the reaction in Equation (2.31) is at equilibrium. The existence of this equilibrium concentration prevents monomer conversion reaching 100 %.

Normally, this equilibrium monomer concentration is too low to detect. A notable exception is α-methylstyrene whose T_c for 100 % monomer concentration is 61 °C, and the equilibrium monomer concentration at 25 °C is 2.2 mol/L [107].

Conventionally, it has been assumed that the propagation rate constant K_p is independent of chain length. Experimental results have shown that K_p is independent of chain length at least for chain lengths > 16 for styrene and > 62 for methyl methacrylate [108]. The propagation rate constant K_p is relatively insensitive to the viscosity of the system except at very high polymer concentrations [88], [109].

It has long been recognized that some bulk polymerizations stop at well below 100 % conversion [110]. This phenomenon has successfully been explained as due to a glassy-state transition of the polymerizing mass [111]. Although the polymerization can proceed very slowly in the glassy state [109], [112], for practical purposes it can be assumed that polymerization stops when the system changes from a viscous liquid to a solid glass. It has been proposed that the initiator efficiency f approaches zero when the system reaches a glassy state [87], [113] and that this is mainly responsible for the cessation of polymerization.

2.2.1.3. Termination

An active center on a growing polymer radical may be destroyed by a variety of processes, including termination by added substances. The latter reactions are called inhibition and retardation processes, and are not considered here. This section discusses bimolecular termination reactions between polymer radicals. Although one of the radicals involved in bimolecular termination may be an initiator radical, under normal polymerization conditions such reactions may be negligible since the concentration of initiator radicals is much smaller than that of polymer radicals.

Bimolecular termination of two polymer radicals can occur by combination or coupling:

(2.33)

or by disproportionation, in which case a hydrogen radical is transferred from one polymer chain to the other. The result is the formation of two polymer molecules, one of which has a terminal double bond.

(2.34)

Termination by combination and disproportionation can occur simultaneously, and the relative importance of these two modes of termi-

nation depends on monomer type and polymerization temperature. Experimental data are not available for many monomers; however, radicals which undergo termination by combination appear exclusively to have the structure (**1**) [114]. A well-known example is styrene, which experiences termination by combination almost exclusively over a wide range of temperatures [114], [115]. On the other hand, radicals which undergo disproportionation and combination may have the structure (**2**).

1 **2**

For methyl methacrylate, combination and disproportionation are both important at low temperature, with disproportionation becoming the dominant mode at high temperatures [116–118].

Since bimolecular termination reactions are intrinsically very fast, these reactions are likely to be diffusion controlled when they involve radical centers on polymeric reactants. The autoacceleration of polymerization rate that is a consequence of diffusion-controlled termination is usually called the gel effect or Trommsdorff – Norrish effect. Figure 8 illustrates the autoacceleration in rate for the polymerization of methyl methacrylate [119]. The interpretation proposed was that the increase in rate is a consequence of a decrease in the rate of termination, due to the large increase in viscosity of the reacting medium, thus giving an increase in radical concentration.

Figure 8. Conversion – time histories for the polymerization of methyl methacrylate in benzene initiated by benzoyl peroxide at 50 °C
The different curves are for various concentrations of monomer in solvent [119]

In general, the termination rate constant should depend on the size of the polymeric radical reactants, the concentration and molecular mass distribution of the accumulated polymer, solvent type, and temperature. As the concentration of entanglement points increases during the course of polymerization, the functional dependence of the termination rate constant on the chain lengths of the polymeric radical reactants should change dramatically. At some high monomer conversion (high polymer concentration) when the polymeric radicals are trapped (diffusion of the center of mass of polymer chains is essentially zero), radical centers may continue to move (due to monomer addition by propagation) and undergo bimolecular termination [118]. With this form of termination, the termination rate constant should be independent of the chain lengths of the polymeric radical reactants. Originally, upon examination of the autoacceleration of the conversion – time curve, it was believed that the termination reaction only became diffusion controlled at some monomer conversion greater than zero and that this occurred when the polymer chains were sufficiently entangled (with a sufficient number of physical entanglement points). It has been recognized that the bimolecular termination reactions may be diffusion controlled even at zero monomer conversion (zero polymer concentration) [114], [120–122]. At low monomer conversions, where polymer chains in a good solvent are isolated coils, translational diffusion of the center of mass of the chains is sufficiently rapid, and the limiting step is the so-called segmental diffusion rate of the radical center in the coil. With limited interpenetration of the coils, a finite and significant time is required for the radical centers on the partially penetrating coils to meet in a suitable reaction volume where bimolecular termination may occur. The probability of finding the radical centers in a suitable reaction volume near the coil surfaces decreases as the coil sizes increase, and, therefore, the termination constant should increase with decreasing polymer molecular mass, with decreasing goodness of the solvent (which depends on the nature and concentration of monomer, inert solvent, and polymer), and with increasing polymer concentration (increasing monomer conversion). It is well known that in dilute solution the poly-

mer coil size decreases with increasing polymer concentration.

At somewhat higher conversions, when there are a sufficient number of chain entanglement points, the translational diffusion rate of the center of mass of polymer coils decreases dramatically and bimolecular termination rates become translationally diffusion controlled. Of course, shorter polymer chains will experience translational diffusion-controlled termination at higher monomer conversions (higher polymer concentrations) than longer chains, and clearly the bimolecular termination rate constant will be chain-length dependent and the bivariate distribution $K_t(r, s)$ will change its shape dramatically with increasing polymer concentration. Finally, when the polymer coils are trapped, K_t should become independent of chain length [118].

Figure 9. Polymerization of acrylamide – rate and molecular mass development ($T = 60\,°C$, $[M]_0 = 3.4$ mol/L, initiated by potassium peroxosulfate $[I]_0 = 5.2 \times 10^{-4}$ mol/L) – – – = Constant K_t; —·— = Use of Equation (2.35) [126]

The mechanisms of diffusion-controlled reactions in polymer systems are being clarified both theoretically and experimentally (see for example [122]), but at present developing a general formulation for K_t for the whole course of polymerization is a formidable task. Considering the complexity of the mechanisms of diffusion-controlled termination reactions, in some cases it may be necessary to use an empirical approach for reactor calculations [96], [97], [123–126]. For example, K_t may be approximated by

$$K_t = K_{t0} \exp\left[-\left(A_1 x + A_2 x^2 + A_3 x^3\right)\right] \tag{2.35}$$

where x is the monomer conversion, K_{t0} is the termination rate constant at zero monomer conversion ($x = 0$), and A_1, A_2, A_3 are adjustable parameters. An application is shown in Figure 9. The adjustable parameters A_1, A_2, A_3 are usually estimated by fitting isothermal conversion – time curves. The adjustable parameters should be functions of temperature and possibly initiator concentration (radical initiation rate). Note that K_t estimated by fitting polymerization rate and number-average molecular masses is a number-average termination rate constant. Although, this termination rate constant may predict rates of polymerization and number-average molecular masses adequately, its use to calculate higher averages will underestimate weight-average, and Z-average molecular mass [88].

Figure 10. Effect of inhibitors and retarders
a) No retarder or inhibitor; b) With retarder; c) With inhibitor

2.2.1.4. Chain Transfer to Small Molecules

During free-radical polymerization, chain transfer to small molecules X may occur. The small molecule may be initiator, monomer, chain-transfer agent, solvent, inhibitor, or impurity. In general, these chain-transfer reactions can be represented by Equations (2.21) and (2.22).

$$R_r^{\bullet} + X \xrightarrow{K_{rX}} P_r + X^{\bullet} \tag{2.21}$$

$$X^{\bullet} + M \xrightarrow{K_p'} R_1^{\bullet} \tag{2.22}$$

When K'_p is approximately zero (i.e., $X^\bullet$ is a stable radical) X is called an inhibitor. If K'_p is smaller than the propagation rate constant K_p, X is called a retarder. Idealized behavior of inhibitors and retarders is shown schematically in Figure 10. The kinetics of inhibition and retardation can be found elsewhere [127].

For an added agent to be a chain-transfer agent, K'_p must be approximately equal to K_p (or $K_p < K'_p$, if chain length is large enough). Therefore, the chain-transfer agent reduces the molecular masses but does not affect rates of polymerization.

The chain-transfer rate constants for most monomers are about 10^4–10^5 times smaller than the propagation rate constant ($K_{fm}/K_p = 10^{-5}$–10^{-4}).

The presence of monomer molecules is inevitable, so that the value of K_{fm}/K_p places an upper limit on the polymer molecular mass that can be obtained with a given monomer. Larger K_{fm} values are observed when the propagating radicals have very high energies (high reactivities), such as in the case of ethylene, vinyl acetate, and vinyl chloride.

2.2.1.5. Kinetics of Linear Polymerization

The elementary reactions involved in linear free-radical polymerization (chains produced are linear with no branches or cross-links) are as follows:

Initiation

$$I \xrightarrow{K_d} 2\,R^\bullet_{in}$$

$$R^\bullet_{in} + M \xrightarrow{K_i} R^\bullet_1$$

Propagation

$$R^\bullet_r + M \xrightarrow{K_p} R^\bullet_{r+1}$$

Chain transfer to monomer

$$R^\bullet_r + M \xrightarrow{K_{fm}} P_r + R^\bullet_1$$

Chain transfer to small molecule (T)

$$R^\bullet_r + T \xrightarrow{K_{fT}} P_r + T^\bullet$$

$$T^\bullet + M \xrightarrow{K'_p} R^\bullet_1$$

Termination by disproportionation

$$R^\bullet_r + R^\bullet_s \xrightarrow{K_{td}} P_r + P_s$$

Termination by combination

$$R^\bullet_r + R^\bullet_s \xrightarrow{K_{tc}} P_{r+s}$$

To derive the kinetic rate equations, the following assumptions are usually made:

1) All rate constants are independent of chain length.
2) Chain lengths are sufficiently large that the total rate of monomer consumption may be equated to the rate of monomer consumption by the propagation reactions alone [this is often called the long-chain approximation (LCA)].
3) Radicals generated in chain-transfer reactions propagate with monomer rapidly and thus do not affect the polymerization rate.
4) The stationary-state hypothesis (SSH) is valid for radical reactions. One can therefore assume that both the rates of radical generation and consumption are much greater than the rate of change of radical concentration with respect to time [128], [129].

Let us first derive an expression for the polymerization rate R_p, applying the above assumptions. The balanced equation for polymer radicals with chain length r is given by

$$\frac{1}{V}\frac{d\,(V\,[R^\bullet_1])}{dt} = R_I + K_{fm}\,[M]\sum_{r=2}^{\infty}[R^\bullet_r] + K'_p\,[T^\bullet]\,[M] - K_{fT}\,[R^\bullet_1]\,[T] - K_p\,[R^\bullet_1]\,[M] - (K_{tc}+K_{td})\,[R^\bullet_1]\,[R^\bullet] \quad (2.36)$$

$$\frac{1}{V}\frac{d\,(V\,[R^\bullet_r])}{dt} = K_p\,[R^\bullet_{r-1}]\,[M] - K_p\,[R^\bullet_r]\,[M] - K_{fm}\,[R^\bullet_r]\,[M] - K_{fT}\,[R^\bullet_r]\,[T] - (K_{tc}+K_{td})\,[R^\bullet_r]\,[R^\bullet] \quad (r \geq 2) \quad (2.37)$$

where R_I is the initiation rate ($R_I = 2K_d f\,[I]$) and $[R^\bullet] = \sum_{r=1}^{\infty}[R^\bullet_r]$, which is the total polymer radical concentration. The transfer radical concentration $[T^\bullet]$ is given by

$$\frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{T}^{\cdot}])}{\mathrm{d}t}=K_{\mathrm{fT}}\,[\mathrm{R}^{\cdot}]\,[\mathrm{T}]-K'_{\mathrm{p}}\,[\mathrm{T}^{\cdot}]\,[\mathrm{M}] \tag{2.38}$$

Applying the stationary-state hypothesis gives

$$K_{\mathrm{fT}}\,[\mathrm{R}^{\cdot}]\,[\mathrm{T}]=K'_{\mathrm{p}}\,[\mathrm{T}^{\cdot}]\,[\mathrm{M}] \tag{2.39}$$

Summation of Equations (2.36) and (2.37) over all chain lengths (1 to infinity) and substituting Equation (2.39) into the sum gives

$$\frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{R}^{\cdot}])}{\mathrm{d}t}=\sum_{r=1}^{\infty}\frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{R}^{\cdot}_{r}])}{\mathrm{d}t}$$
$$=R_{\mathrm{I}}+K'_{\mathrm{p}}\,[\mathrm{T}^{\cdot}]\,[\mathrm{M}]-K_{\mathrm{fT}}\,[\mathrm{R}^{\cdot}]\,[\mathrm{T}]-(K_{\mathrm{tc}}+K_{\mathrm{td}})\,[\mathrm{R}^{\cdot}]^2$$
$$=R_{\mathrm{I}}-(K_{\mathrm{tc}}+K_{\mathrm{td}})\,[\mathrm{R}^{\cdot}]^2 \tag{2.40}$$

Application of the stationary-state hypothesis for the total polymer radical concentration $[\mathrm{R}^{\bullet}]$, gives

$$R_{\mathrm{I}}=K_{\mathrm{t}}\,[\mathrm{R}^{\cdot}]^2 \tag{2.41}$$

where $K_{\mathrm{t}}=K_{\mathrm{tc}}+K_{\mathrm{td}}$. In the above formalism, the termination rate, R_{t} is given by

$$R_{\mathrm{t}}=K_{\mathrm{t}}\,[\mathrm{R}^{\cdot}]^2 \tag{2.42}$$

It is worth noting here that $R_{\mathrm{t}}=2\,K_{\mathrm{t}}\,[\mathrm{R}^{\bullet}]^2$ is often used in the literature, although $R_{\mathrm{t}}=K_{\mathrm{t}}\,[\mathrm{R}^{\bullet}]^2$ is more widely used in free-radical polymerization (e.g., the compilation of kinetic rate constants in [130]). One must distinguish carefully which type of termination rate constant is being used when consulting the literature on polymerization kinetics.

From Equation (2.41), the total polymer radical concentration is given by

$$[\mathrm{R}^{\cdot}]=(R_{\mathrm{I}}/K_{\mathrm{t}})^{0.5} \tag{2.43}$$

Based on the long-chain approximation, the polymerization rate R_{p} is given by

$$R_{\mathrm{p}}=-\frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{M}])}{\mathrm{d}t}=K_{\mathrm{p}}\,[\mathrm{R}^{\cdot}]\,[\mathrm{M}]$$
$$=\left(\frac{K_{\mathrm{p}}}{K_{\mathrm{t}}^{0.5}}\right)R_{\mathrm{I}}^{0.5}\,[\mathrm{M}] \tag{2.44}$$

Since $R_{\mathrm{I}}=2K_{\mathrm{d}}\,f\,[\mathrm{I}]$,

$$R_{\mathrm{p}}=\left(\frac{K_{\mathrm{p}}}{K_{\mathrm{t}}^{0.5}}\right)(2K_{\mathrm{d}}f\,[\mathrm{I}])^{0.5}\,[\mathrm{M}] \tag{2.45}$$

Equation (2.45) predicts a first-order dependenceon monomer concentration and a square-root dependence on initiator concentration, the latter being a direct consequence of the bimolecular nature of the termination reaction.

Now consider the weight chain length distribution $W(r)$. Application of the stationary-state hypothesis for polymer radicals with chain length r (Eq. 2.36 and 2.37) gives.

$$[\mathrm{R}^{\cdot}_{1}] \tag{2.46}$$
$$=\frac{R_{\mathrm{I}}+K_{\mathrm{fm}}\,[\mathrm{M}]\,[\mathrm{R}^{\cdot}]+K_{\mathrm{fT}}\,[\mathrm{T}]\,[\mathrm{R}^{\cdot}]}{K_{\mathrm{p}}\,[\mathrm{M}]+K_{\mathrm{fm}}\,[\mathrm{M}]+K_{\mathrm{fT}}\,[\mathrm{T}]+(K_{\mathrm{tc}}+K_{\mathrm{td}})\,[\mathrm{R}^{\cdot}]}$$

$$[R^{\cdot}_{r}] \tag{2.47}$$
$$=\frac{K_{\mathrm{p}}\,[\mathrm{M}]\left[\mathrm{R}^{\cdot}_{r-1}\right]}{K_{\mathrm{p}}\,[\mathrm{M}]+K_{\mathrm{fm}}\,[\mathrm{M}]+K_{\mathrm{fT}}\,[\mathrm{T}]+(K_{\mathrm{tc}}+K_{\mathrm{td}})\,[\mathrm{R}^{\cdot}]}$$

Let us introduce the following dimensionless groups:

$$\tau=\frac{R_{\mathrm{td}}+R_{\mathrm{f}}}{R_{\mathrm{p}}}=\frac{K_{\mathrm{td}}\,[\mathrm{R}^{\cdot}]+K_{\mathrm{fm}}\,[\mathrm{M}]+K_{\mathrm{fT}}\,[\mathrm{T}]}{K_{\mathrm{p}}\,[\mathrm{M}]} \tag{2.48}$$

$$\beta=\frac{R_{\mathrm{tc}}}{R_{\mathrm{p}}}=\frac{K_{\mathrm{tc}}\,[\mathrm{R}^{\cdot}]}{K_{\mathrm{p}}\,[\mathrm{M}]} \tag{2.49}$$

where

$R_{\mathrm{p}}=K_{\mathrm{p}}\,[\mathrm{R}^{\bullet}]\,[\mathrm{M}]$; propagation rate
$R_{\mathrm{td}}=K_{\mathrm{td}}\,[\mathrm{R}^{\bullet}]^2$; rate of termination by disproportionation
$R_{\mathrm{tc}}=K_{\mathrm{tc}}\,[\mathrm{R}^{\bullet}]^2$; rate of termination by combination
$R_{\mathrm{f}}=K_{\mathrm{fm}}\,[\mathrm{R}^{\bullet}]\,[\mathrm{M}]+K_{\mathrm{fT}}\,[\mathrm{R}^{\bullet}]\,[\mathrm{T}]$; rate of chain transfer.

Since $R_{\mathrm{I}}=R_{\mathrm{td}}+R_{\mathrm{tc}}$, Equations (2.46) and (2.47) can be simplified as follows:

$$[\mathrm{R}^{\cdot}_{1}]=\frac{\tau+\beta}{1+\tau+\beta}\,[\mathrm{R}^{\cdot}] \tag{2.50}$$

$$[R^{\cdot}_{r}]=\frac{1}{1+\tau+\beta}\,[\mathrm{R}^{\cdot}_{r-1}] \tag{2.51}$$

Therefore,

$$[R^{\cdot}_{r}]=[\mathrm{R}^{\cdot}]\,(\tau+\beta)\,\Phi^{r} \tag{2.52}$$

where

$\Phi=1/(1+\tau+\beta)$

Now consider the production rate of polymer molecules with chain length r, $R_{\mathrm{FP}}(r)$, which is given by

$$R_{\mathrm{FP}}(r) = \frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{P}_r])}{\mathrm{d}t} = (K_{\mathrm{fm}}\,[\mathrm{M}] + K_{\mathrm{fT}}\,[\mathrm{T}] + K_{\mathrm{td}}\,[\mathrm{R}^{\cdot}])\,[\mathrm{R}^{\cdot}_r] + \frac{1}{2}K_{\mathrm{tc}}\sum_{s=1}^{r-1}[\mathrm{R}^{\cdot}_s]\,[\mathrm{R}^{\cdot}_{r-s}] \tag{2.53}$$

Substituting for $[\mathrm{R}^{\bullet}_r]$ using Equation (2.52) gives

$$R_{\mathrm{FP}}(r) = K_{\mathrm{p}}\,[\mathrm{R}^{\cdot}]\,[\mathrm{M}]\,(\tau+\beta)\left\{\tau+\frac{\beta}{2}(\tau+\beta)(r-1)\right\}\Phi^r \tag{2.54}$$

The instantaneous weight chain length distribution $W(r)$ is therefore given by

$$W(r) = \frac{rR_{\mathrm{FP}}(r)}{\sum_{r=1}^{\infty} rR_{\mathrm{FP}}(r)} = \frac{(\tau+\beta)\left\{\tau+\frac{\beta}{2}(\tau+\beta)(r-1)\right\}r\Phi^r}{1+\tau+\beta} = (\tau+\beta)\left\{\tau+\frac{\beta}{2}(\tau+\beta)(r-1)\right\}r\Phi^{r+1} \tag{2.55}$$

If $\beta \ll \tau$, that is most polymer chains are formed by chain transfer and/or termination by disproportionation, Equation (2.55) reduces to

$$W(r) = \tau^2 r\Phi^{r+1} = r\left(\frac{1}{1+\tau}\right)^{r-1}\left(\frac{\tau}{1+\tau}\right)^2 \tag{2.56}$$

Here, $1/(1+\tau)$ is the probability of growth for a given polymer radical, and $\tau/(1+\tau)$ is the probability that a polymer radical stops growing. Therefore, Equation (2.56) is essentially the same as the distribution derived for linear step-growth polymerization (Eq. 2.9), based on a statistical argument.

It is sometimes more convenient to describe the chain length distribution as a continuous function rather than a discrete function, and this can often be done with small error as r is usually very large. Therefore, the following approximation may be useful:

$$W(r) \approx (\tau+\beta)\left\{\tau+\frac{\beta}{2}(\tau+\beta)(r-1)\right\}r \cdot \exp\{-(\tau+\beta)\,r\} \tag{2.57}$$

Note that $(\tau+\beta)$ has the value of ca. 10^{-6}–10^{-2} for usual free-radical polymerization $[(\tau+\beta) \ll 1]$.

The weight-average chain length P_{W} for polymer produced instantaneously is given by

$$P_{\mathrm{W}} = \sum_{r=1}^{\infty} rW(r) = \frac{\tau(2+\tau+\beta)+\beta(3+\tau+\beta)}{(\tau+\beta)^2} \approx \frac{2\tau+3\beta}{(\tau+\beta)^2} \tag{2.58}$$

The instantaneous number-average chain length P_{N} is given by

$$P_{\mathrm{N}} = \frac{1}{\sum_{r=1}^{\infty} W(r)/r} = \frac{(1+\tau+\beta)}{(\tau+\beta/2)} \approx \frac{1}{(\tau+\beta/2)} \tag{2.59}$$

The polydispersity index PDI for polymer produced instantaneously is given by

$$\mathrm{PDI} = \frac{P_{\mathrm{W}}}{P_{\mathrm{N}}} \approx \frac{(2\tau+3\beta)(\tau+\beta/2)}{(\tau+\beta)^2} \tag{2.60}$$

If $\beta = 0$, i.e., termination by combination does not occur, the polydispersity index takes on the maximum value, PDI = 2. On the other hand, if $\tau = 0$, i.e., chain termination is solely by bimolecular termination through combination, PDI takes on the minimum value, 1.5. Figure 11 shows the PDI as a function of the fraction of chain termination by bimolecular termination by combination, $\beta/(\tau+\beta)$.

Figure 11. Effect of the type of chain termination on the polydispersity index

The $W(r)$, P_{W}, P_{N}, and PDI derived here give the instantaneous properties. In linear free-radical polymerization the polymer molecules once formed are inert and do not react further.

In general, since the concentrations of monomer, initiator, and chain-transfer agent change with time, the chain length distribution of the accumulated polymer is always broader than the instantaneous distribution. Particularly, when bimolecular termination is strongly diffusion controlled and most of the polymer chains are produced by bimolecular termination, the accumulated distribution broadens significantly with increasing conversion. The polydispersity index PDI for commercial polymers is usually larger than two and this is the result of a drift in molecular mass averages of the instantaneous distribution. The accumulated distribution and its averages can be calculated as follows:

$$\bar{W}(r) = \frac{1}{x}\int_0^x W(r)\,\mathrm{d}x \tag{2.61}$$

$$\bar{P}_\mathrm{W} = \frac{1}{x}\int_0^x P_\mathrm{W}\,\mathrm{d}x \tag{2.62}$$

$$\bar{P}_\mathrm{N} = \frac{x}{\int_0^x \frac{1}{P_\mathrm{N}}\,\mathrm{d}x} \tag{2.63}$$

$$\overline{\mathrm{PDI}} = \frac{\bar{P}_\mathrm{W}}{\bar{P}_\mathrm{N}} \tag{2.64}$$

Superscript bars denote accumulated properties. These integrals may be replaced with equivalent ordinary differential equations which then can be solved by using readily available differential equation solvers. The variation of the kinetic parameters of $W(r)$ with respect to conversion must be known to calculate the accumulated properties. In a similar manner, accumulated molecular mass properties may be calculated for semi-batch and continuous reactors. In a well mixed flow reactor with an ideal residence time distribution (CSTR), the chain length distribution produced is the instantaneous distribution. In batch reactors the distribution is therefore broader [131], [132]. Other mathematical techniques to derive the distribution functions can be found elsewhere [29], [32], [33], [133–135].

2.2.1.6. Effect of Temperature

In free-radical polymerization initiated by the thermal decomposition of an initiator, the polymerization rate is given by Equation (2.45), and the effect of temperature can be estimated by the change in the ratio of three rate constants, $K_\mathrm{p}\,(K_\mathrm{d}/K_\mathrm{t})^{0.5}$. Since each kinetic rate constant is considered to follow the Arrhenius equation, the activation energy of polymerization E_R is given by

$$E_\mathrm{R} = E_\mathrm{p} + \frac{E_\mathrm{d}}{2} - \frac{E_\mathrm{t}}{2} \tag{2.65}$$

where E_p, E_d, E_t are activation energies for propagation, initiator decomposition, and bimolecular termination. Typical values for E_p, E_d, E_t are 30, 120, and 15 kJ/mol, respectively. Therefore, E_R is ca. 80 kJ/mol and this is largely due to the very high activation energy for initiator decomposition. The high activation energy for polymerization means that the rate of polymerization increases strongly with increasing temperature. With redox initiation, E_d is ca. 40 kJ/mol and therefore E_R is considerably smaller at ca. 40 kJ/mol. With radiation initiation, E_d is close to zero and E_R is ca. 20 kJ/mol.

Now consider the effect of temperature on the molecular mass of polymer obtained. For a simple example, consider the case where $\tau \ll \beta$, that is, termination by combination produces most of the polymer chains. Equation (2.58) gives

$$P_\mathrm{W} \propto \frac{1}{\beta} = \frac{K_\mathrm{p}\,[\mathrm{M}]}{K_\mathrm{tc}\,(2K_\mathrm{d} f\,[\mathrm{I}]/K_\mathrm{tc})^{0.5}} \propto \frac{K_\mathrm{p}}{(K_\mathrm{tc}K_\mathrm{d})^{0.5}} \tag{2.66}$$

The activation energy for average chain lengths E_L is given by

$$E_\mathrm{L} = E_\mathrm{p} - \frac{E_\mathrm{d}}{2} - \frac{E_\mathrm{t}}{2} \tag{2.67}$$

With initiators E_L is about -40 kJ/mol. The average chain lengths decrease significantly with increasing temperature when initiators are used and bimolecular termination controls molecular mass development (most of the polymer chains are produced by bimolecular termination). With radiation initiation, E_L is about 20 kJ/mol and molecular masses increase moderately with temperature.

When unimolecular termination (chain transfer to small molecules) dominates in the production of polymer chains, E_L is given by

$$E_\mathrm{L} = E_\mathrm{p} - E_\mathrm{f} \tag{2.68}$$

where E_f is the activation energy for the chain-transfer reaction. E_f depends on the type of chain-transfer agent, but usually $E_p - E_f < 0$, and therefore molecular masses usually decrease with increasing temperature when unimolecular termination (chain transfer to small molecules) controls molecular mass development.

2.2.1.7. Branching Reactions

For the elementary reactions shown in Section 2.2.1.4, radical centers are always located on chain ends, and the dead polymer chains are chemically inert and are all linear. Branched or cross-linked polymer can be obtained by chemical treatment of linear chains using processes such as vulcanization, radiation, and melt processing with peroxides. This section, however, is mainly concerned with branching reactions which may occur during polymerization. Branched and cross-linked polymers are of significant commercial interest, but quantitative interpretation has been limited due to a lack of analytical techniques for the comprehensive characterization of branched polymers. Some of the newer analytical techniques are summarized in [136–138].

Chain Transfer to Polymer. Chain transfer to polymer involves the abstraction of an atom from the backbone of a polymer chain and results in the formation of a backbone radical center. Monomer addition to this radical center produces a tri-branching point and a long-chain branch whose average length is equal to that of the primary chains produced at the same instant.

(2.69)

Chain transfer to polymer may be neglected at low monomer conversions as polymer concentrations are low. However, under more practical situations where polymerizations are carried to very high conversions, it may be important. In emulsion polymerization the polymer concentration in polymer particles is relatively high even near zero conversion and therefore long-chain branching reactions are more significant in emulsion than in solution or bulk polymerization. Examples of monomers for which long-chain branching via chain transfer to polymer is important include ethylene and vinyl acetate.

When long-chain branching is important the calculation of the full molecular mass distribution requires excessive computation. However, the leading moments and molecular mass averages can be readily calculated by using the method of moments for an infinite set of differential equations which describe the chemical kinetics [61], [134], [139–147]. The i-th order moment of the polymer distribution can be defined by

$$Q_i = \sum_{t=1}^{\infty} r^i \, [\mathrm{P}_r] \tag{2.70}$$

Therefore, the number- and weight-average chain lengths of the accumulated polymer are given by $\bar{P}_N = Q_1/Q_0$ and $\bar{P}_W = Q_2/Q_1$, respectively. For the elementary reactions shown in Section 2.2.1.4 plus Equation (2.69), some of the lower order moments for batch polymerization are given by [61], [145–147]:

$$\frac{1}{V_0}\frac{\mathrm{d}\,(VQ_0)}{\mathrm{d}x} = \tau + \beta/2 \tag{2.71}$$

$$\frac{1}{V_0}\frac{\mathrm{d}\,(VQ_1)}{\mathrm{d}x} = 1 \tag{2.72}$$

$$\frac{1}{V_0}\frac{\mathrm{d}\,(VQ_2)}{\mathrm{d}x} = \frac{2\,(1+C_{p2})}{\tau+\beta+C_{p1}} + \frac{\beta\,(1+C_{p2})^2}{(\tau+\beta+C_{p1})^2} \tag{2.73}$$

with initial conditions: $Q_0 = Q_1 = \ldots\ldots = 0$ at $x = 0$, where

$$C_{pi} = \frac{K_{fp} Q_i}{K_p\,[\mathrm{M}]}$$

$$\tau = \frac{K_{td}\,[\mathrm{R}^{\cdot}] + K_{fm}\,[\mathrm{M}] + K_{fT}\,[\mathrm{T}]}{K_p\,[\mathrm{M}]}$$

$$\beta = \frac{K_{tc}\,[\mathrm{R}^{\cdot}]}{K_p\,[\mathrm{M}]}$$

and V_0 is the initial volume of the reacting mixture. Figure 12 shows calculated weight-average chain lengths for a range of the kinetic parameters, keeping τ and β constant with conversion. Note that reactions involving the addition of a

polymer radical center to a double bond on the end of a polymer chain are not accounted for in the moment equations above (Eq. 2.71 and 2.73).

	a	b	c	d	e
τ	1×10^{-4}	1×10^{-4}	1×10^{-4}	1×10^{-4}	1×10^{-4}
β	1×10^{-5}	1×10^{-4}	5×10^{-6}	1×10^{-5}	1×10^{-4}
K_{fp}/K_p	1×10^{-4}	1×10^{-4}	1×10^{-3}	1×10^{-3}	1×10^{-3}

Figure 12. Weight-average chain length development during polymerization with chain transfer to polymer [147]

It is of interest to know whether chain transfer to polymer can lead to gelation. FLORY [148], [149] predicted that this reaction type would not cause gelation without the assistance of other interlinking processes. By application of Equation (2.73) it has been clearly shown that chain transfer to polymer plus termination by disproportionation (i.e., there is no termination by combination) can never cause gelation. With termination by combination, however, gelation can occur under certain circumstances [61], [145], [147].

In general, when long-chain branching occurs, the molecular mass distribution broadens. This is especially true for polymerization in a continuous stirred-tank reactor as the reacting mixture always has a relatively high polymer concentration. Comparing long-chain branching frequencies in batch and CSTR reactors at the same monomer conversion levels shows that the residence time distribution of the CSTR favors branching [150], [151].

Figure 13. Effect of temperature on the number-average chain length of polyisobutylene and isobutene – isopropene copolymer [161]
a) Polyisobutylene with $AlEtCl_2$ as initiator; b) Polyisobutylene with BF_3 as initiator; c) Polyisobutylene with $AlCl_3$ as initiator; d) Isobutene – isopropene with BF_3 as initiator; e) Isobutene – isopropene with $AlEtCl_2$ as initiator; f) Isobutene – isopropene with $AlCl_3$ as initiator

When the reactivity of polymer radicals is high (as with polyethylene), intramolecular chain transfer (transfer to a location on its own chain) or backbiting may occur. In this case polymer chains with short branches are formed. In the synthesis of low-density polyethylene (LDPE) by high-pressure free-radical polymerization, short-chain branching frequencies are high (typically 20 – 40 branches per 1000 backbone carbon atoms). For polyethylene, the amount of short-chain branching is about ten times greater than long-chain branch-

ing. For polyethylene the backbiting reaction can be represented as follows

(2.74)

with $n = 3$ and 4 most probable [152].

Reactions with Double Bonds in Polymer Chains. When a radical center on the end of a polymer chain adds to a double bond on the end of a polymer chain, a tri-branching point is formed.

(2.75)

Terminal double bonds on the ends of polymer chains may be formed by chain transfer to monomer, termination by disproportionation, and by β-scission at backbone radical centers.

Reaction with double bonds located on the polymer backbone (internal or pendant double bonds) leads to formation of tetra-branching centers.

(2.76)

Pendant double bonds are obtained when monomers containing two or more reactive double bonds are polymerized. For example, the homopolymerization of a diene and the copolymerization of vinyl and divinyl monomers produces polymer chains with pendant double bonds. The photopolymerization of multifunctional monomers is used in surface coatings and in the replication of optical discs [153–155]. For densely cross-linked systems the buildup of radical concentration is so rapid that the stationary-state hypothesis may not be valid. Superabsorbent polymers used in diapers and porous organic packagings used in size exclusion chromatography are lightly cross-linked polymeric networks. The kinetics of copolymerization of vinyl and divinyl monomers are discussed in more detail in Section 2.3.3.

2.2.2. Ionic Polymerization

The energy required to form a pair of ions from a neutral molecule is large, and therefore these very unstable ions must be stabilized by solvation at low temperature before polymerization will occur. Polar solvents cannot be used to solvate ions because they are overly reactive and destroy the ionic initiators. Ionic polymerizations are usually carried out at low temperature in solvents of low polarity. These solvents may give ion pairs as well as free ions. Thus, a propagating ionic chain may have a counterion close to the active center during its growth. The proximity of the ion on the growing chain to its counterion depends on the type of counterion, which is determined by the initiator type, and the solvation power of the solvent. Therefore, unlike free-radical polymerization the type of initiator and the nature of the solvent have a large effect on monomer addition during chain growth. The propagation rate constant, therefore, depends not only on temperature but also on the type of initiator and the type and amount of solvent.

For ionic chain-growth polymerizations in solvents with high solvating power where the distance between the propagating active center and the counterion is large, the factors governing the stereochemistry are similar to those for free-radical polymerization. However, in solvents with poor solvating power, there may be extensive coordination between initiator, propagating chain end, and monomer, which results in isotactic (or syndiotactic) placements almost exclusively, i.e., stereospecific polymerization occurs.

Unlike radical polymerization, bimolecular termination between active centers does not occur in ionic polymerization. Termination of an active center on a polymer chain occurs by reaction with the counterion, solvent, monomer, or other species. Often, the initiation reactions are very fast, and the initiator is consumed in the

early stages of polymerization before the polymer chains have grown much beyond oligomeric size. In the absence of unimolecular termination a population of polymer chains having the same molecular mass can grow. The concentration of ionic reactive centers is usually much larger than that of radical centers. Ionic polymerization kinetics are not as well understood as those radical-based polymerizations because of the requirements of extreme purity for the components of the reacting mixture.

Elastomers such as butyl rubber and polyisoprene; high-density polyethylene; polypropylene and its copolymers are widely produced by ionic polymerization. Polypropylene of high molecular mass cannot be produced by radical polymerization. In addition to carbon – carbon double bonds, carbonyl double bonds [81], [82], alkynes [156], and carbon – nitrogen double bonds [157] can be polymerized via ionic mechanisms. However, the discussion here is limited to carbon – carbon double bonds.

2.2.2.1. Cationic Polymerization

Cationic polymerization proceeds through attack on the monomer by an electrophilic species, resulting in heterolytic splitting of the double bond to produce a carbenium ion [158], [159].

(2.77)

The most important commercial high polymers produced by cationic polymerization are polyisobutylenes and butyl rubber (a copolymer of isobutylene and a 1,3-diene, usually isoprene). A typical polymerization is carried out at about $-100\,°C$ in chlorinated solvents such as chloromethane and is initiated by $AlCl_3$. The polymerization is very fast.

In the following section, interesting features of cationic polymerization are discussed, but no attempt is made to develop quantitative rate expressions. Carbenium ions are very sensitive to polar impurities and this often precludes the establishment of a stationary state. It is also difficult to establish what proportion of the initiator produces growing polymer chains.

Cationic polymerization of vinyl monomers is essentially limited to those with electron-donating substituents such as 1,1-dialkyl, alkoxy, phenyl or vinyl groups. Cationic polymerization involves initiation, propagation, termination, and chain transfer to small molecules much as in free-radical polymerization.

To initiate cationic polymerization, protonic acids such as H_2SO_4, $HClO_4$, and H_3PO_4 or Lewis acids such as BF_3, $AlCl_3$, $TiCl_4$, and $SnCl_4$ are used. Lewis acids are by far the most important initiators for industrial cationic polymerizations. Initiation with Lewis acids requires the presence of a trace of proton donor such as water, alcohol, and organic acid or a cation donor such as alkyl halide.

$$AlCl_3 + (CH_3)_3CCl \rightleftharpoons (CH_3)_3C^+(AlCl_4)^- \tag{2.78}$$

$$(CH_3)_3C^+(AlCl_4)^- + CH_2{=}CH(X) \longrightarrow (CH_3)_3CCH_2{-}C^+(X)H(AlCl_4)^- \tag{2.79}$$

In general,

$$I + ZY \overset{K}{\rightleftharpoons} Y^+(IZ)^- \tag{2.80}$$

$$Y^+(IZ)^- + M \xrightarrow{K_i} YM^+(IZ)^- \tag{2.81}$$

Most polymerizations exhibit a maximum rate at some ratio of initiator and coinitiator concentrations. This optimum ratio varies widely from one initiator system to another and in some instances the solvent has an effect on the ratio. (Note that it has also been proposed that the protogen or catinogen be referred to as the initiator, and the Lewis acid as coinitiator [159], although conventional terminology is exactly the reverse.)

The propagation reaction involves the successive insertion of monomers into the partial bond between the propagating species and its counterion.

$$YM_n^+(IZ)^- + M \xrightarrow{K_p} YM_{n+1}^+(IZ)^- \tag{2.82}$$

The apparent propagation rate constant K_p depends on the type of initiator and solvent used. In general, K_p becomes larger as the acidity of the initiator and/or the dielectric constant of the solvent increases. This is due to the fact that the reactivity of free ions in monomer addition is much greater than that of ion pairs.

A wide variety of reactions may lead to termination of chain growth in cationic polymerization, but it is usually ambiguous and difficult to distinguish termination reactions from chain-transfer reactions. Chain transfer to monomer is most often responsible for the formation of dead polymer:

$$YM_n^+(IZ)^- + M \xrightarrow{K_{tm}} M_n + YM^+(IZ)^- \qquad (2.83)$$

If the counterion is sufficiently nucleophilic, termination by combination may occur:

$$YM_n^+(IZ)^- \xrightarrow{K_t} YM_nIZ \qquad (2.84)$$

However, this reaction is not very common. In fact, true termination in which the activity of a chain carrier is lost without regeneration of an active center is very rare if no impurities capable of destroying an active center are present. However, since the carbenium ion is highly reactive, it would be a formidable task to remove all these impurities from the reaction components. Under commercial conditions it is likely that active centers are consumed to a significant extent by impurities. Termination reactions in cationic polymerizations are unimolecular, as they are in anionic and in anionic-coordination polymerization. Generally, for cationic systems the polymerization rate is given by

$$R_p = K\,[M]^{1-3}\,[I] \qquad (2.85)$$

The first-order rate with respect to initiator concentration is a consequence of the fact that termination reactions are unimolecular. The overall activation energy for polymerization E_R may be ca. -40 to 60 kJ/mol [160]. For many polymerization systems E_R is negative and the rather unusual phenomenon of increasing polymerization rate with decreasing temperature is observed. The activation energy for the degree of polymerization is always negative, and therefore the average chain length decreases with increasing temperature. Usually, cationic polymerizations can produce polymer with sufficient molecular mass only at very low temperatures. Figure 13 shows the Arrhenius plot for the number-average chain length [161]. There is a change in the slope of this plot around $-100\,°C$. This has been attributed to a change in the chain termination step from chain transfer to monomer below $-100\,°C$ to chain transfer to solvent above $-100\,°C$.

Table 1. Effect of counterion on the propagation rate constants (K_p^- and $K_p^{\pm}$) in the anionic polymerization of styrene in THF at 25 °C

Counterion	$K_p^{\pm}$	K_p^-	$K \times 10^7$
Li^+	160	6.5×10^4	2.2
Na^+	80	6.5×10^4	1.5
K^+	60–80	6.5×10^4	0.8
Rb^+	50–80	6.5×10^4	0.1
Cs^+	22	6.5×10^4	0.02

2.2.2.2. Anionic Polymerization

Anionic polymerizations show many of the same characteristics as cationic polymerizations. However, since the nature of carbanions is different from carbenium ions, there are distinct differences. In contrast to cationic polymerization, neither termination nor chain transfer occur in many anionic polymerizations (living polymerization) especially when polar substances are absent. Anionic active centers are usually much more stable than cationic active centers. Although anionic polymerizations proceed rapidly at low temperatures, they are not usually as temperature sensitive as cationic polymerizations, and polymerizations usually proceed well at ambient temperature and higher.

A variety of basic initiators have been used to initiate anionic polymerizations [162], [163]. The initiation involves the addition of an anion (base) to the double bond of the monomer.

(2.86)

where the $C^- \cdots G^+$ bond can have character ranging from partially covalent to completely ionic. Alkyllithium initiators have been most widely used in the polymerization of butadiene and isoprene, since they are easy to prepare and are soluble in hydrocarbon solvents. A complication which arises when alkyllithiums are used

in nonpolar solvents such as benzene, toluene, cyclohexane, and *n*-hexane is association of various organolithium species. This phenomenon is important, since the associated species are essentially unreactive in propagation [162], [164].

Propagation occurs by the successive insertion of monomers into the partial bond between the propagating anion and its cationic counterion.

(2.87)

The polymerization rate is fundamentally expressed by $R_p = K_p\,[M]\,[M^-]$, where $[M^-]$ is the concentration of active species. When nonpolar solvents such as dioxane are used, all active species may be ion pairs. However, in polar solvents such as THF, the effect of dissociation to free ions on polymerization rate cannot be neglected. Therefore, the propagation rate is given by the sum of the rates for free propagating anions (R^-) and for ion pairs, $R^-(G^+)$.

$$R_p = K_p^- \,[R^-]\,[M] + K_p^{\pm}\,[R^-\,(G^+)]\,[M] \tag{2.88}$$

The two propagating species are in equilibrium,

$$R^-(G^+) \overset{K}{\rightleftharpoons} R^- + G^+ \tag{2.89}$$

where K is the dissociation constant and is given by

$$K = [R^-]\,[G^+]\,/\,[R^-\,(G^+)] \tag{2.90}$$

Some experimental values for $K_p^{\pm}$ and K_p^- are listed in Table 1 [165], [166]. Consider the simple example of the anionic polymerization of styrene in THF at 25 °C, initiated by sodium naphthalide with an initial concentration $[I] = 1 \times 10^{-3}$ mol/L. Assuming the initiation reaction is instantaneous, $[R^-] = 1.22 \times 10^{-5}$ and $[R^-\,(G^+)] = 9.88 \times 10^{-4}$ mol/L. Therefore,

$$\frac{K_p^-\,[R^-]\,[M]}{K_p^{\pm}\,[R^-\,(G^+)]\,[M]} = \frac{(6.5 \times 10^4)\,(1.22 \times 10^{-5})}{(80)\,(9.88 \times 10^{-4})} = 10.0 \tag{2.91}$$

As shown here, although the concentration of free ions is only 1.2 % of the total propagating species, approximately 90 % of the monomer is consumed by the free ion.

Since carbanions are relatively stable, anionic polymerization with carefully purified reagents may lead to systems in which chain termination is absent. Such polymers are referred to as living polymers [167], [168].

Let us now develop an expression for the chain length distribution for living polymer. Assuming that initiation is instantaneous, the total number of growing chains N_I is constant throughout the polymerization. Now a monomer molecule adds to a polymer chain as shown in Figure 14. The probability that it adds to polymer chain (1) is $1/N_I$, and that it does not add to polymer chain (1) is $1 - 1/N_I$. Therefore, when N_M monomer units have been consumed and bound into polymer chains the probability that a randomly selected polymer chain possesses r monomer units is given by a binomial distribution:

$$N\,(r) = \left(\frac{N_M}{r}\right)\left\{\frac{1}{N_I}\right\}^r \left\{1 - \frac{1}{N_I}\right\}^{N_M - r} \tag{2.92}$$

$N\,(r)$ is also the number chain length distribution. Since $1/N_I \ll 1$ and r is large, the binomial distribution reduces to the Poisson distribution:

$$N\,(r) = \frac{e^{-\eta}\eta^r}{r!} \tag{2.93}$$

where $\eta = N_M/N_I$, which is equal to the number-average chain length, $\bar{P}_N$.

Figure 14. Schematic drawing for the derivation of chain length distribution in living polymerization

The weight chain length distribution $W\,(r)$ and the weight-average chain length $\bar{P}_W$ are given by

$$W(r) = \frac{rN(r)}{\sum_{r=1}^{\infty} rN(r)} = \frac{e^{-\eta}\eta^{r-1}}{(r-1)!} \tag{2.94}$$

$$\bar{P}_W = \sum_{r=1}^{\infty} rW(r) = \eta + 1 \tag{2.95}$$

Therefore, the polydispersity index $\overline{PDI}$ is given by

$$\overline{PDI} = \bar{P}_W / \bar{P}_N = 1 + 1/\bar{P}_N \tag{2.96}$$

With sufficiently large average chain length, the polydispersity should approach unity. To obtain a narrow molecular mass distribution (MWD), the rate of initiation should be greater than the rate of propagation. Polystyrenes having polydispersity as low as 1.01 have been synthesized by using sodium naphthalide as initiator, and these are widely used in the calibration of gel permeation chromatography. It is of interest to note that narrow MWD can be obtained even when there are two reactive site types (free ion and ion pair). This is a result of the equilibrium between the site types, and growing chains will have both site types attached to their ends for the same fraction of time during their growth.

Sequential addition of monomers to a living anionic polymerization system is at present the most useful method for synthesizing well-defined block copolymers.

2.2.2.3. Ziegler – Natta Polymerization

Due to the interactions between the propagating chain end, counterion, and incoming monomer molecule, ionic polymerizations tend to give stereospecific polymers. Polar monomers such as methacrylates and vinyl ethers undergo stereospecific polymerization initiated by conventional ionic initiators under certain conditions. However, the coordinating power of the Ziegler – Natta initiators is much stronger than the usual ionic initiators, so it is appropriate to treat Ziegler – Natta (ZN) systems separately. The use of ZN initiators for diene polymerization has yielded remarkable results that far surpass the stereospecificity exhibited by organolithium initiators. With butadiene, four different stereospecific polymer structures, namely, *cis*-1,4, *trans*-1,4, syndiotactic-1,2, and isotactic-1,2 can each separately be obtained to almost total exclusion of the others by an appropriate choice of initiator system, as shown in Table 2 [169].

The ZN initiators are the only ones which can be used to polymerize α-olefins such as propene and 1-butene. Although the phenomenon of stereoisomerism is not applicable to the symmetrical ethylene, the use of ZN initiators produces a polyethylene with much less long-chain branching than that obtained by free-radical polymerization.

The ZN initiators consist of a combination of alkyls or hydrides of group 1 – 3 metals with salts of group 4 – 8 metals. Some of the components of ZN initiators are as follows:

Group 1 – 3 metal	Transition metal
$(C_2H_5)_3Al$, $(C_2H_5)_2AlCl$	$TiCl_4$, $TiCl_3$, VCl_3
$(C_2H_5)AlCl_2$, $(C_2H_5)_2Be$	$VOCl_3$, $Ti(OC_4H_9)_4$
$C_5H_{11}Na$	$CrCl_3$, $MnCl_3$

The titanium – aluminum initiator systems, especially $(C_2H_5)_3Al - TiCl_3$, have been most thoroughly studied. Many important ZN initiators are solids and during polymerization are suspended in liquid or gaseous media. Heterogeneous initiator systems appear to be necessary for the production of isotactic polyolefins, although soluble initiators are used for the synthesis of syndiotactic polypropylene.

Discussions on the mechanism of ZN polymerization can be found elsewhere [169–173]. At present, however, none of the proposed mechanisms have been comprehensively verified and the observed kinetics are usually quite complex. Some examples of the initial stages of heterogeneous ZN polymerization are shown in Figure 15 [174]. The particles of the transition metal component usually consist of aggregates of smaller crystals, so that when the particle size of the transition metal component is relatively larger (curves c and d), the mechanical pressure of the growing polymer chains cleaves the particles. This increases both the surface area of the initiator and the number of active sites. After this initial period, a steady-state rate may be observed. The time required to reach this steady-state can be reduced by initially using smaller particles. When the transition metal particles are ground or crushed to a very small size just before the polymerization, the rate of polymerization increases rapidly and exceeds the steady-state values (curves a and b). This phenomenon may in-

Table 2. Stereospecific polymerization of butadiene [169]

Ziegler-type catalyst		Conditions	Structure of polymer*, %		
Metal alkyl	Transition metal salt		1,2	*cis*-1,4	*trans*-1,4

* 
dicate the existence of highly active but short-lived sites. This kind of behavior can be avoided by aging the initiator system prior to addition of monomer.

Figure 15. Effect of previous physical treatment on a sample of α–$TiCl_3$ on the propene polymerization rate (in grams C_3H_6 per gram $TiCl_3$ per hour) at constant pressure and temperature
a), b) Ground α–$TiCl_3$ (sizes $\leq 2\,\mu m$); c), d) Unground α–$TiCl_3$ (sizes $1-10\,\mu m$)

Many ZN polymerizations exhibit a continuous decrease in rate rather than reaching a steady-state in which the rate curve reaches a maximum and then continues to decline. The rate of decline varies with the polymerization system used. The decline in polymerization rate has been attributed to (1) a decrease in the number of active centers, (2) a lowering of activity of individual active centers due to structural changes, and (3) a lowering of activity of individual active centers due to encapsulation by polymer.

In this section a very simple example is considered, too approximate to accurately describe real systems, but useful to illustrate a model building process. Consider the following polymerization scheme [175].

1) Adsorption of monomer (M) on the active site

$$\mathrm{M} + \mathrm{A} \xrightarrow{K_A} \mathrm{P}_1^* \tag{2.97}$$

where P_1^* is a growing chain with unit chain length and A is a vacant active site.

2) Propagation

$$\mathrm{P}_r^* + \mathrm{M} \xrightarrow{K_P} \mathrm{P}_{r+1}^* \tag{2.98}$$

where P_r^* is the growing polymer chain with length r

3) Desorption of polymer chain from the active site

$$\mathrm{P}_r^* \xrightarrow{K_D} \mathrm{P}_r + \mathrm{A} \tag{2.99}$$

where P_r is a dead polymer molecule with chain length r.

Assuming that the polymer chain is sufficiently long (long-chain assumption), the polymerization rate R_p is given by

$$R_p = K_p\,[\mathrm{P}^*]\,[\mathrm{M}] \tag{2.100}$$

where [P∗] is the total concentration of active sites, namely, $[P^*] = \sum_{r=1}^{\infty} [\mathrm{P}_r^*]$.

If the stationary-state hypothesis is applied to [P∗],

$$K_A\,[M]\,[A] = K_D\,[P^*] \tag{2.101}$$

Each active site is either occupied by growing polymer chains or is vacant. Denoting the total concentration of adsorption sites by $[A]_0$,

$$[A]_0 = [A] + [P^*] \tag{2.102}$$

Combining Equations (2.101) and (2.102) gives

$$[P^*] = K\,[A]_0\,[M] / (1 + K\,[M]) \tag{2.103}$$

where $K = K_A/K_D$. Therefore, the polymerization rate is given by

$$R_p = K_p K\,[A]_0\,[M] / (1 + K\,[M]) \tag{2.104}$$

Next consider the instantaneous molecular mass distribution for this process. The population balance equations for growing polymer chains are

$$\frac{1}{V}\frac{d\left(V\,[P_1^*]\right)}{dt} = K_A\,[M]\,[A] - K_p\,[M]\,[P_1^*] - K_D\,[P_1^*] \tag{2.105}$$

$$\frac{1}{V}\frac{d\,(V\,[P_r^*])}{dt} = K_p\,[M]\left[P_{r-1}^*\right] - K_p\,[M]\,[P_r^*] - K_D\,[P_r^*] \quad (r \geq 2) \tag{2.106}$$

By application of the SSH for $[P_r^*]$,

$$[P_1^*] = \frac{1}{1+\tau'}\,[A] \tag{2.107}$$

$$[P_r^*] = \frac{1}{1+\tau'}\left[P_{r-1}^*\right] \tag{2.108}$$

where $\tau' = K_D/(K_p\,[M])$. Therefore,

$$[P_r] = K_D\,[P_r^*] = K_D\,[A]\left(\Phi'\right)^r \tag{2.109}$$

where $\Phi' = 1/(1 + \tau')$.

The number and weight chain length distributions are given by

$$N(r) = \frac{[P_r]}{\sum_{r=1}^{\infty}[P_r]} = \left(1-\Phi'\right)\left(\Phi'\right)^{r-1} \tag{2.110}$$

$$W(r) = \frac{r\,[P_r]}{\sum_{r=1}^{\infty} r\,[P_r]} = r\left(1-\Phi'\right)^2\left(\Phi'\right)^{r-1} \tag{2.111}$$

where Φ' is the probability that a growing polymer chain adds another monomer molecule, and $(1 - \Phi')$ is the probability that a growing chain stops growing.

Therefore, Equations (2.110) and (2.111) are essentially the same as Equations (2.8) and (2.9) or Equation (2.56). The polydispersity index (PDI) for instantaneously formed polymer is two.

An interesting feature of heterogeneous ZN initiators is the very broad MWD of the polymers produced, although the above simple model predicts PDI = 2 for instantaneously formed polymer. The PDI of accumulated polymer may be 10 or higher. In the case of copolymerization, the compositional heterogeneity is also large even when monomer ratios are kept constant during polymerization. Presently, there are two main theories which try to explain these large dispersities, namely, the presence of a distribution of activities for the active sites or diffusional effects which limit the transport of reactants to the active sites [176].

2.3. Copolymerization

Copolymerization permits the synthesis of an almost unlimited number of polymer types and is therefore often used to obtain a better balance of properties for commercial applications. Copolymers may be synthesized by chain-growth and step-growth polymerization. In step-growth polymerization, different monomers with the same type of functional group generally show only minor differences in reactivity. As a result, most copolymers prepared by step-growth polymerization contain essentially random placements of repeat units, with the composition of the copolymers essentially the same as those of the original monomer mixture.

In contrast, strong selective effects often occur in chain-growth copolymerizations, and the composition of the copolymer formed may differ greatly from the composition of the original monomer mixture. This section deals exclusively with chain-growth copolymerization. Chain-growth copolymerization can be carried out with various types of active centers including free-radical, cationic, and anionic species. Free-radical copolymerization is most commonly used due to its higher alternating tendencies.

2.3.1. Copolymer Composition

The composition of copolymers cannot be determined from a knowledge of the homopolymerization rates of each monomer. In 1944, the instantaneous copolymer composition equation was proposed independently by several researchers by assuming that the chemical activity of a propagating chain depends solely on the terminal monomer unit on which the active center is located [177–180]. This model is called the terminal model, and the copolymer chain can be considered as a first-order Markov chain. For binary systems, the following four propagation reactions are possible.

$$\mathrm{P}^*_{m,n,1} + \mathrm{M}_1 \xrightarrow{K_{11}} \mathrm{P}^*_{m+1,n,1} \tag{2.112}$$

$$\mathrm{P}^*_{m,n,1} + \mathrm{M}_2 \xrightarrow{K_{12}} \mathrm{P}^*_{m,n+1,2} \tag{2.113}$$

$$\mathrm{P}^*_{m,n,2} + \mathrm{M}_1 \xrightarrow{K_{21}} \mathrm{P}^*_{m+1,n,1} \tag{2.114}$$

$$\mathrm{P}^*_{m,n,2} + \mathrm{M}_2 \xrightarrow{K_{22}} \mathrm{P}^*_{m,n+1,2} \tag{2.115}$$

where $\mathrm{P}^*_{m,n,1}$ is a live copolymer chain with m units of monomer 1 (M_1) and n units of monomer 2 (M_2) bound in the polymer chain and with the active center located on terminal monomer unit 1.

The reactivity of the propagating species may be affected by the penultimate monomer unit. In such cases, the model is referred to as the penultimate model or a second-order Markov chain [181], [182] and propagation consists of eight reactions. Further expansion is possible by considering the effects of remote units preceding the penultimate unit, such as the pen-penultimate model [183–185].

It is customarily assumed that the propagation rate constants are independent of chain length and that the chains are sufficiently large (long-chain assumption, LCA). The LCA includes the approximation that monomer consumed in reactions other than propagation is negligible and that the SSH is valid for each type of active center; i.e., the rate of formation of any type of active center is equal to its rate of consumption. Statistically, these conditions are equivalent to the statistical stationary condition [185–187].

Now consider a binary copolymerization whose propagation reactions follow the terminal model. The specific polymerization rates of monomers 1 and 2 are given by

$$-\frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{M}_1])}{\mathrm{d}t} = K_{11}\,[\mathrm{P}^*_1]\,[\mathrm{M}_1] + K_{21}\,[\mathrm{P}^*_2]\,[\mathrm{M}_1] \tag{2.116}$$

$$-\frac{1}{V}\frac{\mathrm{d}\,(V\,[\mathrm{M}_2])}{\mathrm{d}t} = K_{12}\,[\mathrm{P}^*_1]\,[\mathrm{M}_2] + K_{22}\,[\mathrm{P}^*_2]\,[\mathrm{M}_2] \tag{2.117}$$

where $[\mathrm{P}^*_1]$ and $[\mathrm{P}^*_2]$ are the total concentrations of active centers of types 1 and 2 with

$$[\mathrm{P}^*_1] = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty}[\mathrm{P}^*_{m,n,1}] \tag{2.118}$$

$$[\mathrm{P}^*_2] = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty}[\mathrm{P}^*_{m,n,2}] \tag{2.119}$$

Application of the SSH gives

$$K_{21}\,[\mathrm{P}^*_2]\,[\mathrm{M}_1] = K_{12}\,[\mathrm{P}^*_1]\,[\mathrm{M}_2] \tag{2.120}$$

Dividing Equation (2.116) by Equation (2.117) and using Equation (2.120) gives the instantaneous copolymer composition equation:

$$\frac{F_1}{F_2} = \frac{-\mathrm{d}\,(V\,[\mathrm{M}_1])}{-\mathrm{d}\,(V\,[\mathrm{M}_2])} = \frac{[\mathrm{M}_1]\,(r_1\,[\mathrm{M}_1] + [\mathrm{M}_2])}{[\mathrm{M}_2]\,([\mathrm{M}_1] + r_2\,[\mathrm{M}_2])} \tag{2.121a}$$

or

$$F_1 = \frac{r_1 f_1^2 + f_1 f_2}{r_1 f_1^2 + 2 f_1 f_2 + r_2 f_2^2} \tag{2.121b}$$

where F_1 and F_2 are the mole fractions of monomers 1 and 2 in the copolymer produced instantaneously, and f_1 and f_2 are the mole fractions of unreacted monomer. The reactivity ratios are defined by

$$r_1 = \frac{K_{11}}{K_{12}} \tag{2.122}$$

$$r_2 = \frac{K_{22}}{K_{21}} \tag{2.123}$$

It is straightforward to extend this method to multicomponent polymerization [188–190]. Note that Equation (2.121 a or b) is strictly valid only for infinitely long polymer chains and its application to short chains may introduce significant error [191–193].

When applying Equation (2.121 a or b), it is usually assumed that all of the copolymer chains

have the same composition. However, since the chain length of a copolymer is finite, the composition and chain lengths of the individual polymer molecules cannot all be identical. Therefore, for copolymer chains produced instantaneously there is a bivariate distribution of composition and chain length [194–200]. The variance of the copolymer composition distribution is approximately inversely proportional to the chain length and, therefore, for sufficiently long chains it may be reasonable to neglect the composition distribution. In order to treat oligomeric molecules, application of discrete mathematics such as the finite Markov chain theory [184], [201] is necessary.

In batch copolymerization, there is a compositional drift due to the change in the composition of the unreacted monomer mixture with time. The total monomer conversion x is related to the mole fraction f_1 of unreacted monomer 1 by the following equation [202]:

$$\frac{\mathrm{d}f_1}{\mathrm{d}x} = \frac{f_1 - F_1}{1 - x} \tag{2.124}$$

$f_1 = f_{10}, F_1 = F_{10}$ at $x = 0$.

Therefore, if the relationship between f_1 and F_1 is known, Equation (2.124) can be solved numerically. If the terminal model is applicable to a binary system (Eq. 2.121 a or b), Equation (2.124) can be integrated analytically to obtain the following equation [203–208]:

$$x = 1 - \left(\frac{f_1}{f_{10}}\right)^{\alpha} \left(\frac{f_2}{f_{20}}\right)^{\beta} \left(\frac{f_{10} - \delta}{f_1 - \delta}\right)^{\gamma} \tag{2.125}$$

where
$\alpha = r_2/(1 - r_2)$,
$\beta = r_1/(1 - r_1)$,
$\gamma = (1 - r_1 r_2)/\{(1 - r_1)(1 - r_2)\}$
$\delta = (1 - r_2)/(2 - r_1 - r_2)$.

Except for copolymerizations at the azeotropic point, there will be some compositional drift. (At the azeotropic point, the composition of the instantaneously produced copolymer and of the unreacted monomers is the same; hence in a batch reactor there is no compositional drift at this point.) An example of compositional drift during batch polymerization is shown in Figure 16 [208]. One method to avoid compositional drift is to use a continuous stirred-tank reactor with an ideal residence time distribution. In this instance, the STOCKMAYER instantaneous bivariate distribution of chain length and composition will be obtained. Another method of composition control is to use semi-batch operation in which monomers are fed to maintain a constant ratio of monomer concentrations in the reactor [209], [210].

Figure 16. Batch copolymerization of styrene (M_1) and methyl methacrylate (M_2) at 60 °C for $f_{10} = 0.8$, $f_{20} = 0.2$, $r_1 = 0.53$, $r_2 = 0.56$
$\bar{F}_1$ and $\bar{F}_2$ are the accumulated mole fraction of monomer 1 and 2 bound in the copolymers.

In the terminal model, monomer sequence-length distribution depends only on the product of reactivity ratios $r_1 r_2$ [211], [212]. In free-radical copolymerizations $r_1 r_2$ is generally less than unity, indicating a higher alternating tendency. The styrene – maleic anhydride system is an example of a very highly alternating one with both r_1 and r_2 very close to zero. For ionic copolymerizations, there is a general lack of any tendency towards alternation, and $r_1 r_2$ is usually close to or greater than unity. Generally, in free-radical copolymerization, the reactivity ratios are relatively insensitive to the reaction medium and temperature. However, in ionic copolymerization, temperature and reaction medium can significantly affect reactivity ratios.

Traditional methods for estimating reactivity ratios [177], [213–215] are based on the transformation of the instantaneous copolymer composition equation into a form that is linear in the parameters r_1 and r_2. While these linearizations provide simple techniques for parameter estimation, they are generally statistically invalid be-

cause the independent variable has experimental error and the dependent variable does not have a constant variance [216–223]. Both of the latter assumptions are necessary for the linear least squares method to be a statistically valid estimation method. Although it has been shown that proper experimental design can allow the use of linear least squares analysis [222], [224], the estimation of the reactivity ratios is a typical example of a problem in nonlinear estimation. Reactivity ratios are now generally estimated by application of procedures based on the statistically valid error-in-variables-model (EVM) [220], [221], [225–230]. These methods allow all the sources of experimental error to be accounted for.

In spite of the fact that reactivity ratios obtained using invalid estimation procedures have often been used, the copolymer composition equation based on the terminal model has given useful predictions. It is generally ineffective to use the copolymer composition equation for comparing models. Information on the copolymer microstructure (e.g., monomer sequence length distribution) is needed to compare the validity of terminal and penultimate models [179], [231], [232]. Advancements in NMR techniques have provided suitable information on sequence length distribution. However, cases have been reported in which sequence length distribution information does not permit model discrimination [233].

As will be discussed in Section 2.3.2 the composition equation includes the rate constants of elementary reactions only in ratios, while the rate equation is dependent on their absolute values, and therefore success of the former equation does not insure success of the latter [234].

2.3.2. Kinetics of Copolymerization

Consider the kinetics of free-radical copolymerization of monomers M_1 and M_2, assuming the terminal model is applicable. Important elementary reactions are:

Initiation

$$\mathrm{I} \xrightarrow{K_d} 2\,\mathrm{R}^{\bullet}_{in}$$
$$\mathrm{R}^{\bullet}_{in} + \mathrm{M}_1 \xrightarrow{K_1} \mathrm{R}^{\bullet}_{1,0,1}$$
$$\mathrm{R}^{\bullet}_{in} + \mathrm{M}_2 \xrightarrow{K_2} \mathrm{R}^{\bullet}_{0,1,2}$$

Propagation

$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{M}_1 \xrightarrow{K_{11}} \mathrm{R}^{\bullet}_{m+1,n,1}$$
$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{M}_2 \xrightarrow{K_{12}} \mathrm{R}^{\bullet}_{m,n+1,2}$$
$$\mathrm{R}^{\bullet}_{m,n,2} + \mathrm{M}_1 \xrightarrow{K_{21}} \mathrm{R}^{\bullet}_{m+1,n,1}$$
$$\mathrm{R}^{\bullet}_{m,n,2} + \mathrm{M}_2 \xrightarrow{K_{22}} \mathrm{R}^{\bullet}_{m,n+1,2}$$

Transfer to monomer

$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{M}_1 \xrightarrow{K_{f11}} \mathrm{P}_{m,n} + \mathrm{R}^{\bullet}_{1,0,1}$$
$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{M}_2 \xrightarrow{K_{f12}} \mathrm{P}_{m,n} + \mathrm{R}^{\bullet}_{0,1,2}$$
$$\mathrm{R}^{\bullet}_{m,n,2} + \mathrm{M}_1 \xrightarrow{K_{f21}} \mathrm{P}_{m,n} + \mathrm{R}^{\bullet}_{1,0,1}$$
$$\mathrm{R}^{\bullet}_{m,n,2} + \mathrm{M}_2 \xrightarrow{K_{f22}} \mathrm{P}_{m,n} + \mathrm{R}^{\bullet}_{0,1,2}$$

Transfer to small molecule

$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{T} \xrightarrow{K_{fT1}} \mathrm{P}_{m,n} + \mathrm{T}^{\bullet}$$
$$\mathrm{R}^{\bullet}_{m,n,2} + \mathrm{T} \xrightarrow{K_{fT2}} \mathrm{P}_{m,n} + \mathrm{T}^{\bullet}$$

Termination by disproportionation

$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{R}^{\bullet}_{r,s,1} \xrightarrow{K_{td11}} \mathrm{P}_{m,n} + \mathrm{P}_{r,s}$$
$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{R}^{\bullet}_{r,s,2} \xrightarrow{K_{td12}} \mathrm{P}_{m,n} + \mathrm{P}_{r,s}$$
$$\mathrm{R}^{\bullet}_{m,n,2} + \mathrm{R}^{\bullet}_{r,s,2} \xrightarrow{K_{td22}} \mathrm{P}_{m,n} + \mathrm{P}_{r,s}$$

Termination by combination

$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{R}^{\bullet}_{r,s,1} \xrightarrow{K_{tc11}} \mathrm{P}_{m+r,n+s}$$
$$\mathrm{R}^{\bullet}_{m,n,1} + \mathrm{R}^{\bullet}_{r,s,2} \xrightarrow{K_{tc12}} \mathrm{P}_{m+r,n+s}$$
$$\mathrm{R}^{\bullet}_{m,n,2} + \mathrm{R}^{\bullet}_{r,s,2} \xrightarrow{K_{tc22}} \mathrm{P}_{m+r,n+s}$$

where $\mathrm{R}^{\bullet}_{m,n,1}$ is a polymer radical with m units of monomer 1 (M_1) and n units of monomer 2 (M_2) bound in the polymer chain with active center located on monomer unit 1. $P_{m,n}$ is a polymer molecule with m units of monomer 1 and n units of monomer 2. The polymerization rate, R_p is given by

$$\begin{aligned} R_p &= K_{11}[\mathrm{R}^{\bullet}_1][\mathrm{M}_1] + K_{12}[\mathrm{R}^{\bullet}_1][\mathrm{M}_2] \\ &\quad + K_{21}[\mathrm{R}^{\bullet}_2][\mathrm{M}_1] + K_{22}[\mathrm{R}^{\bullet}_2][\mathrm{M}_2] \\ &= K_p[\mathrm{R}^{\bullet}][\mathrm{M}] \end{aligned} \tag{2.126}$$

where $[\mathrm{R}^{\bullet}_1]$ and $[\mathrm{R}^{\bullet}_2]$ are given by Equations (2.118) and (2.119) and $[\mathrm{R}^{\bullet}] = [\mathrm{R}^{\bullet}_1] + [\mathrm{R}^{\bullet}_2]$, $[\mathrm{M}] = [\mathrm{M}_1] + [\mathrm{M}_2]$, and K_p is defined by

$$K_p = (K_{11}f_1 + K_{12}f_2)\varphi^{\bullet}_1 + (K_{21}f_1 + K_{22}f_2)\varphi^{\bullet}_2 \tag{2.127}$$

where $f_1 = [M_1]/[M]$, and $\varphi_1^{\bullet} = [R_1^{\bullet}]/[R^{\bullet}]$.

Equation (2.127) is an example of a pseudo-kinetic rate constant [145–147], [209], [210], [235–238]. For an N-component system, the pseudo-kinetic rate constants can be defined as follows

Propagation

$$K_p = \sum_{\substack{i=1\\j=1}}^{N} K_{ij}\,\varphi_i^{\bullet} f_j \tag{2.128}$$

Chain transfer to monomer

$$K_{fm} = \sum_{\substack{i=1\\j=1}}^{N} K_{fij}\,\varphi_i^{\bullet} f_j \tag{2.129}$$

Chain transfer to small molecule

$$K_{fT} = \sum_{i=1}^{N} K_{fT_i}\,\varphi_i^{\bullet} \tag{2.130}$$

Termination by disproportionation

$$K_{td} = \sum_{\substack{i=1\\j=1}}^{N} K_{td_{ij}}\,\varphi_i^{\bullet}\,\varphi_j^{\bullet} \tag{2.131}$$

Termination by combination

$$K_{tc} = \sum_{\substack{i=1\\j=1}}^{N} K_{tc_{ij}}\,\varphi_i^{\bullet}\,\varphi_j^{\bullet} \tag{2.132}$$

Even though these pseudo-kinetic rate constants depend on the monomer mole fraction and change with time in a batch reactor, the simplification achieved when dealing with multicomponent polymerizations is very great. Furthermore, since the mole fraction of each polymer radical type $\varphi_i^{\bullet}$ is independent of chain length for sufficiently long chains, these same pseudo-kinetic rate constants can be used to calculate molecular mass distribution as well as polymerization rate [61],[235] . Therefore, by using pseudo-kinetic rate constants, a multicomponent polymerization reduces to a homopolymerization, and therefore Equations (2.55) – (2.64) are all applicable for copolymerization. With appropriate definitions for pseudo-kinetic rate constants, this method may also be usefully applied when copolymerization kinetics follow the penultimate model [235].

In the early development of the kinetics of copolymerization, chemically controlled bimolecular termination was assumed to be operable [239–241]. However, since these reactions have been shown to be diffusion controlled [120–122], [242], Equations (2.131) and (2.132) must be modified by using appropriate models which account for this. In this context, the use of the cross-termination factor, $\varphi = K_{t12}/(K_{11}K_{12})^{0.5}$, is not acceptable. Several models for diffusion-controlled termination of binary copolymerization have been proposed. Atherton and North [243], [244] proposed the following for the termination constant.

$$K_t = K_{t11}F_1 + K_{t22}F_2 \tag{2.133}$$

The mole fractions of monomers bound in polymer chains F_1 and F_2 can be calculated by using the copolymer composition equation. On the other hand, Russo and Munari [245] proposed the use of penultimate effect for the termination reactions since segmental diffusion is highly dependent on the last two portions of the chain.

Until the mid 1980s, a prevailing view of copolymerization kinetics was that the propagation process is, in most cases, correctly described by the terminal model, whereas the termination process involves complexity still to be elucidated. However, it has also been speculated that it is the propagation step that needs further study, while the termination step is well described by simple models such as Equation (2.133), and the penultimate effect on propagation reactions is being examined from the point of view of copolymerization rates [233], [246–252].

2.3.3. Copolymerization of Vinyl and Divinyl Monomers

The use of the terms vinyl and divinyl here is not according to their strict definitions. Here, a vinyl monomer is defined as a monomer with a single reactive double bond (a double bond which will readily add to a radical center) and a divinyl monomer is a monomer which has two such double bonds.

The free-radical copolymerization of vinyl and divinyl monomers is important in the manufacture of ion-exchange resins, chromatographic packings, superabsorbent polymers (with a rapidly growing market in baby diapers and

Figure 17. A schematic drawing of a cross-linked polymer network synthesized by free-radical copolymerization of vinyl and divinyl monomer

promise of the same in several other market areas), cross-linked latex polymers, and other products. Figure 17 shows a schematic of a polymer network synthesized by copolymerization of vinyl and divinyl monomers. There may be many radical centers on the polymer network during polymerization since the mobility of radical centers chemically bound to the network can be highly restricted. Strong autoacceleration in polymerization rate has been reported during network formation by free-radical copolymerization [253–260]. The live double bonds located on polymer chains are called pendant double bonds. Kinetic behavior of radical centers on polymer chains and of pendant double bonds are the most important factors influencing the kinetics of network formation during free-radical polymerization. From the point of view of the mobility of chains, network polymers may be considered as a heterogeneous reaction system, and the formation of microgels before the gel point is reached may be a general feature of network formation in free-radical polymerization [257], [261–265]. The number-average molecular mass between cross-links M_c is important from the point of view of the elastic properties of a gel molecule. As the mole fraction of divinyl monomer increases, the heterogeneity of the polymer network (i.e., regions having very different M_c) becomes significant [265–268].

Reactivity ratios for the copolymerization of vinyl and divinyl monomers are rather difficult to determine. If the reactivities of both double bonds on the divinyl monomer are the same and independent, and cyclization does not occur, the conventional copolymer composition equation (Eq. 2.121 a or b) is still valid when monomer concentration is replaced by double bond concentration and the reactivity ratios defined with respect to each type of double bond are used [269]. However, difficulties generally arise due to the complicated behavior of pendant double bonds, which may react inter- and intramolecularly, and whose reactivity may differ from that of monomer double bonds. At the moment when a divinyl monomer is chemically bound in a polymer chain, another double bond on the just-reacted divinyl monomer may be the nearest neighbour of the active center, and therefore cyclopolymerization may occur under certain conditions. For example, the free-radical polymerization of diallyl quaternary ammonium salts gives soluble, not cross-linked polymers with little or no residual unsaturation [270], [271].

(2.134)

In general, cyclization may also involve two or more monomer units. Since cyclization reactions are controlled by the conformational statistics of the sequence of bonds and do not follow the conventional rate law, larger cycles, formed when an active center adds to a pendant double bond on its own chain or to two double bonds on another chain, may also affect the copolymer composition even when the terminal model is applicable. Various copolymer composition equations which account for cyclization reactions have been proposed [272–276]; however, it may be difficult to apply these equations to higher mole fractions of divinyl monomer or to high monomer conversions. Strictly speaking, in order to know the copolymer composition, it is necessary to know the kinetic behavior of pendant double bonds completely; that is, a knowledge of the reactivity ratios r_1 and r_2 is insufficient to estimate the change in composition during copolymerization. However, r_1 and r_2 are usually obtained without taking into account the monomer consumed by active centers located on just-reacted pendant double bonds. Such parameters may be better regarded as empirical parameters which do not reflect the chemical reactivity of radical centers with double bonds, and they may change with monomer conversion.

As for the kinetics of network formation, fundamental models which assume an equilibrium system (see Section 2.1.3) have been extensively applied to chain-growth polymerization [39], [43], [51], [52], [148], [277–279]. However, chain-growth polymerizations are kinetically controlled, so that the application of the conventional approaches may be in error. It has been shown that under FLORY's simplifying assumptions, namely that (1) the reactivities of all types of double bonds are equal, (2) all double bonds react independently of one another, and (3) there are no intramolecular reactions in finite molecules, the predictions of kinetic and equilibrium models are the same [61], [147], [280]. However, none of the above idealized assumptions are strictly applicable to a real system [265], [281–287]. Kinetic models for network formation by free-radical polymerization are being developed [61], [62], [145–147], [288–295]. Figure 18 shows the change in the average chain length and weight fraction of gel during network formation in the copolymerization of methyl methacrylate and ethylene glycol dimethacrylate [147].

3. Polymerization Processes and Reactor Modeling

3.1. Introduction

The polymer reactor model is now becoming accepted as a valuable tool whose use contributes significantly to all aspects of process technology for polymer manufacture. This includes process design, optimization, state estimation, and control. Through process design, polymers with a unique and desirable combination of properties can often be obtained. Process parameters such

as residence time distribution (RTD) are usually not considered by polymer synthesis chemists, although RTD can influence chemical composition distribution (CCD), molecular mass distribution (MWD), long-chain branching (LCD) and gel/sol ratios. In the early days of the polymer industry, the chemist played the major role in product and process development and scale-up. This has changed, with the process engineer now playing a significant role in all phases of commercialization of new and improved polymer products. His broad experience with process fundamentals and computer modeling are essential to obtain high-quality products, safely and economically.

Dynamic reactor models can be used in a variety of ways. Stability and control of polymer reactors should be considered at the design stage and control problems minimized then, rather than take corrective action after the plant is built. Complex interactions which are involved in polymerization (highly nonlinear temperature and concentration effects) preclude optimal design based on experimentation alone because the cost would be prohibitive. Models can be used to identify potential sources of product variability and strategies to minimize their effects. Models can be used to store information on process technology in a concise and readily retrievable and modifiable form.

Process models can be used to train chemists, chemical engineers, and plant operators and give them a feel for the dynamics of the polymerization process.

The most expensive aspect of model development is experimental estimation of model parameters; highly instrumented bench-, pilot-scale, and plant-scale reactors are required. Statistically designed experiments should be performed to permit efficient parameter estimation and model development. Modeling is an iterative process and the very act of developing a deterministic model permits a greater understanding of the relevant microscopic processes which occur during polymerization or polymer modification. As additional data (plant, pilot-plant, and bench-scale) become available, model structure and parameters can be updated.

This section considers recent developments in polymerization/polymer modification processes and discusses advances in polymer reactor modeling, state estimation, and control.

3.2. Processes and Reactor Modeling for Step-Growth Polymerization

3.2.1. Types of Reactors and Reactor Modeling

In step-growth polymerization, high molecular mass polymers are usually not produced until the final stage of reactions, so that thermal control and mixing of the reaction mixture do not present serious problems in the earlier stages. However, since the final stage of polymerization is very important for the production of polymers with high molecular mass, handling of very high viscosities and temperatures and high interfacial area to remove small molecules are required. Various polymerization processes and reactor types, both for batch and continuous production, have been proposed. Examples of reactors for high viscosities are shown in Figures 19 and 20. Careful selection of the polymerization reactor is very important to produce high-quality polymers [296], [297].

Figure 19. Vertical cone ribbon blade reactor (Mitsubishi Heavy Industries)

Figure 20. Horizontal high-viscosity reactor

The batch reactor is the most versatile reactor type and is used extensively for specialty polymers at low production volumes. Some examples of step-growth polymerizations carried out in such reactors are nylon 6, phenol – formaldehyde, urea – formaldehyde, and melamine – formaldehyde. In polycondensation reactions, it may be necessary to remove condensation products to attain sufficient conversion. When the volume of the reaction mass decreases continuously with time, such reactors are called semi-batch reactors. (A tank-type reactor which does not operate at steady state is defined as a semi-batch reactor). For example, in the production of poly(ethylene terephthalate), PETP, since methanol or ethylene glycol evaporates during polymerization, the batchwise production of PETP is considered a semi-batch operation.

On the other hand, newer high-capacity plants often use continuous processes. The first approximation for a continuous process is a model that consists of plug flow reactors (PFR) and continuous stirred-tank reactors (CSTR) in various combinations (Fig. 21), although various nonideal effects such as flow pattern in the reactor, mass- and heat-transfer limitations, and residence time distribution must be considered for a detailed analysis and design of real reactors [298–302].

Molecular mass distribution of linear polymers produced by step-growth polymerization in a batch or a PFR basically follows the most probable distribution [303]. (Note that batch reactor and PFR are, in principle, equivalent). The molecular mass distribution may be controlled by varying its reaction path if the reaction system is in a nonequilibrium state. Assuming irreversible step-growth polymerization without interchange reactions, the effect of reactor types, such as homogeneous CSTR, segregated CSTR and PFR with a recycle loop, on molecular mass distribution have been considered [301], [302], [304], [305]. An important feature of step-growth polymerization is that the variance of the molecular mass distribution is smallest in a batch reactor or PFR and is largest in a homogeneous CSTR, which is quite contrary to that for chain-growth polymerization. This result may be disappointing, since it is, in principle, impossible to produce polymers whose polydispersity index M_W/M_N is smaller than two in step-growth polymerization at sufficiently high conversions. The polydispersity index of polymers produced in a batch reactor is given by $1+p$, as shown in Section 2.1.1., where p is the conversion of the functional group. However, in commercial polymeric materials, polymers with narrower distributions are not always superior to those with broader distributions, since various levels of properties are required at the same time. The use of a cascade of CSTRs and/or PFRs with recycle loops may be one method to obtain a molecular mass distribution with a polydispersity index larger than two. However, in practice, these methods may have shortcomings because they need a long start-up period and, therefore, problems may occur with the stability of the reaction system. A method in which additional monomers are fed intermediately to a batch reactor or a PFR has been proposed [306]. Theoretical analysis of this intermediate monomer feed method has also been carried out [307], and it has been shown that the polydispersity index can be easily controlled over a wide range with values greater than 2.

In a batch reactor, the reverse reactions and the interchange reactions (redistribution reactions) do not change the MWD from the most probable distribution [303], [308–310]. However, these reactions do change the MWD of polymers produced in CSTR, PFR with a recycle

Figure 21. Representative models for polymerization reactors
A) CSTR + PFR; B) CSTR + CSTR + PFR; C) PFRs; D) CSTRs

loop, and intermediate monomer feed method. Some consideration of these reactions in a CSTR is given in [311]. Qualitatively, these effects lower the polydispersity and make the MWD approach the most probable distribution. This result seems reasonable, since any MWD approaches the most probable distribution with a polydispersity index of two when polymer chains are severed randomly [312], [313].

Other than the common reactor types discussed above, other special types of reactor system may be applied. For example, in the polymerization of urethanes, the reaction rates are so high that reaction takes place even when the monomers are being mixed and pumped into molds. In situ polymerization to form the desired articles directly from monomeric liquids is known as reaction injection molding (RIM) [314], [315]. A schematic of the RIM process is shown in Figure 22. The RIM processing of polyesters, epoxy resins, polyamides, and dicyclopentadienes has also been introduced, although more than 95 % of the total produced by RIM is polyurethane [315]. In the RIM process, the reaction is almost complete by the time the material fills the mold, and therefore the mixing and flow equations must be solved simultaneously with those for chemical reactions in a rational model for these complex situations.

In the finishing stage of nylon 6, nylon 66, and PETP polymerizations, higher molecular mass polymers may be obtained by solid-state polymerization in which polymerization occurs by heating chips or flakes of a material below its melting point in a stream of hot gases in a fluidized bed or in a drier operated under vacuum [316–320]. The monomer, condensation products, and various byproducts diffuse out, and further reaction takes place inside the solid. The progress of these types of reaction is affected significantly by the diffusion of the condensation products and the morphology of the solid.

Although step-growth polymerization has a very long history, a systematic kinetic treatment like that available for free-radical polymerization does not exist because of limitations due to system-specific side reactions and the scarcity of reliable kinetic data. However, this synthetic route is becoming more important due to the development of materials synthesized by step-growth polymerization such as aramides, PPS, PEK, and PES. The production technology of step-growth polymers seems to have revived as an attractive research area and is enjoying a Renaissance period.

3.2.2. Specific Processes

Polyamides (see also → Polyamides) are manufactured by two basic routes. One of these is synthesis from cyclic monomers such as lactams. Polymerization of these substances requires ring opening and subsequent chain growth. Another class of synthetic polyamides is formed from diamines and diacids.

The most common types of polyamides are nylon 6 and nylon 66. The term nylon is often used for synthetic aliphatic polyamides. One number indicates that the product was prepared from a single monomer and represents the number of carbon atoms in the repeating unit. Two numbers refer to the number of carbon atoms in the diamine and that in the diacid, respectively.

Nylon 6 is typically produced by the hydrolytic polymerization of ε-caprolactam [321–325], although polymers with higher molecular mass can be produced by ionic polymerization [321], [323], [326]. The major reactions in the hydrolytic polymerization are

1) Ring opening of ε-caprolactam by water (Eq. 3.1), which produces aminocaproic acid (ACA)
2) Polycondensation of ACA (Eq. 3.2)
3) Acid-catalyzed polyaddition (ring-opening polymerization) by nucleophilic attack of the amine nitrogen on the lactam (Eq. 3.3)

Step-growth polymerization of the amino acid (Eq. 3.2) accounts for only a few percent of total polymerization of ε-caprolactam. However, step-growth polymerization is important since it usually determines the final degree of polymerization at equilibrium. The molecular mass distribution is essentially the most probable distribution, except for the presence of monomer and cyclic oligomers. Since low molecular mass substances lower the polymer quality, they are usually removed by leaching or vacuum treatment of the polymer melt. The formation of cyclic oligomers is an important side reaction [327–329]. For the simulation and optimization of polymerization reactors, only small ring formation or overall ring formation is considered to make the analysis easier [330–333].

Various types of polymerization reactors have been proposed both for batch and continuous processes. A commonly used industrial reactor for a continuous process is a tubular reactor such as the conventional VK column (Vereinfacht Kontinuierliches Rohr) [321], [322], [334], which consists of a vertical tube operating at atmospheric pressure. The feed enters the top of the column and is heated to ca. 220 – 270 °C. The simplest model for this type of reactor is a PFR. However, according to impulse response experiments, the flow is approximately laminar rather than plug flow [322], [335], and the reactor should be modeled as a CSTR followed by

a tubular reactor when a large quantity of water is used since a significant convection current and mixing is provided by the evaporating water [322].

Nylon 66 is manufactured by polycondensation of hexamethylenediamine and adipic acid [336], usually in a multistage process. First, nylon salt (hexamethylenediammonium adipate) is prepared from stoichiometric quantities of hexamethylenediamine and adipic acid in water. The salt can easily be separated by precipitation with methanol.

$$H_2N(CH_2)_6NH_2 + HOOC(CH_2)_4COOH \longrightarrow \begin{bmatrix} {}^{-}O_2C(CH_2)_4CO_2^{-} \\ H_3\overset{+}{N}(CH_2)_6\overset{+}{N}H_3 \end{bmatrix} \quad (3.4)$$

Figure 23. Continuous melt polymerization of nylon 66

The use of nylon salt guarantees the presence of equimolar amounts of $-NH_2$ and $-COOH$ groups. Close control of diamine–diacid balance is important to control the final polymer molecular mass and reactive end groups.

Nylon 66 is fairly unstable at high temperatures in the presence of oxygen. Not only degradation but also cross-linking may occur. Because of this instability, polymerization used to be carried out solely in batch processes. However, complete elimination of oxygen has made it possible to carry out continuous polymerization. An example of a continuous melt polymerization process is shown in Figure 23. The aqueous nylon salt solution is heated to above 200 °C at > 17 bar in an oxygen-free atmosphere. Thereafter, the pressure is reduced to atmospheric and vapor is separated from polymer to promote polymerization to the desired high molecular mass. It has also become possible to polymerize molten hexamethylenediamine and adipic acid directly [330], [336]. Polymerization can also be completed in the solid state.

Several kinetic studies on the synthesis of nylon 66 have been published [337–341]. However, more information is necessary for detailed simulation and optimization of nylon 66 reactors.

Polyesters (see also → Polyesters). The production of high molecular mass polyesters differs somewhat from that of polyamides. In the case of nylons, the chemical equilibrium favors the polyamide under polymerization conditions. With polyester formation, however, the equilibrium is much less favorable. In order to drive the reaction in the forward direction, the condensation product must be removed continuously, usually by application of high vacuum. For polyester reactors, a high vacuum, a high temperature, and a high interfacial area with sufficient surface renewal are required, especially at high conversions.

Both saturated and unsaturated polyesters are produced. Among the saturated polyesters, poly(ethylene terephthalate), PETP, is produced in the largest quantity, and is used for production of fibers, films, molding plastics, and beverage containers. In this section, the engineering aspects of PETP formation are illustrated as an example of a polyester production process.

There are two major routes to synthesize PETP industrially, although the objective in each case is to obtain an intermediate product – i.e., bis(hydroxyethyl)terephthalate (BHET).

Two major routes to synthesize BHET are ester interchange of dimethyl terephthalate (DMT) and direct esterification of terephthalic acid.

Figure 24 shows an example of the PETP production process via the ester interchange route. The ester interchange reaction

(3.5)

is operated in the temperature range 150 – 210 °C at atmospheric pressure. The use of a catalyst is common [342], [343]. The methanol and ethylene glycol (EG) emerging from the reactor are passed through a rectifying column and EG is fed back to the reactor. It is very difficult to force the ester interchange reaction to completion, and therefore after a particular conversion (usually 90 – 95 %), the reaction mixture is passed on to the polycondensation stage. The reaction mixture consists of oligomers of various types. Oligomers with degrees of polymerization as high as three may be formed [342], [344], [345]. Several reactor models for both batch and continuous processes have been proposed [342–350]. An optimization study showed that the ester interchange reactor should be operated initially at high temperature to obtain high conversion; the temperature should be lowered to reduce side reactions [343], [348].

Figure 24. Continuous polymerization process of PETP via ester interchange route

In the polycondensation stage, the reaction temperature is raised to 265 – 285 °C to keep the reaction mixture molten and polymerization fast.

(3.6)

For PETP production, a dual catalyst system in which one component is specially active for ester interchange and the other for polymerization is quite often used [351]. The production of high molecular mass polymer requires the complete removal of ethylene glycol due to the unfavorable equilibrium, and therefore a vacuum is applied. Especially in the final stage of the polycondensation reaction, a very high vacuum is required since the reaction system becomes highly viscous. Consideration of the limitations of mass and heat transfer is very important. Various types of reactors such as rotating disc contactors, wiped film reactors, partially filled screw extruders have been developed as finishers for the polycondensation reaction [342], [343], [350]. Details of fluid mechanics, mixing, and mass and heat transfer characteristics are required for a rational analysis and design of such high-viscosity reactors. In addition to polycondensation reactions, various side reactions must also be considered since a very high temperature is used.

Melt polycondensation of PETP is not generally carried out beyond a particular extent of polymerization since the degradation reactions dominate the process and the product quality may suffer from various undesirable byproducts. To attain higher molecular masses, the products may be subjected to solid-state polymerization [316–320]. Newer processes, especially for beverage and food containers, prefer to stop melt polymerization at lower conversion, and solid-state polymerization is extensively applied.

Direct esterification of terephthalic acid (TPA) and ethylene glycol was generally not preferred earlier because of the difficulties in the purification of TPA due to its low solubility and high melting point. However, with improvements in technology, the direct esterifica-

Figure 25. Continuous polymerization process of PETP via direct esterification route

tion method has been gaining in importance. The process is claimed to give polyesters with superior quality due to their low content of carboxyl end groups and diglycol linkages [351]. In the modeling of this process, aside from the difficulties caused by the various reactions and mass balances involved, it is necessary to take account of the heterogenity of the reactions due to the low solubility of TPA in EG. Simulation and control of the direct esterification reactors is reported in [343], [350], [352–354]. Figure 25 shows a flow diagram of a continuous process for PETP production by direct esterification.

3.3. Processes and Reactor Modeling for Chain-Growth Polymerization

3.3.1. Material Balance Equations for Batch, Semi-Batch, and Continuous Reactors

The following material balance equations apply for multicomponent polymerization, accommodate operation of a well-stirred reactor (no spatial variations in temperature and concentrations), and may be used to simulate different comonomer systems under a variety of operating conditions. Bulk (suspension) and solution polymerizations are considered first; extensions required for multiphase systems (emulsion, inverse emulsion, suspension, dispersion, and gas-phase processes) may be found elsewhere [355]. Special cases where spatial variations in temperature and concentrations are important (e.g., in tubular reactors or packed beds) are also considered.

Bulk, solution, and suspension polymerization systems are characterized by the fact that all of the reactions proceed in a single phase with no spatial variations in temperature and concentration. A model for a reactor carrying out such polymerizations would consist of a set of material balances giving the rates of accumulation, inflow, outflow and a reaction source (sink) term for the various monomers, initiators, chain-transfer agents, and polymer in the reactor. These balance equations are now given in general form

Monomer balances:

$$\mathrm{d}N_i/\mathrm{d}t = F_{i,\mathrm{in}} - (N_i/V)\,V_{\mathrm{out}} - R_{\mathrm{p}_i}V \tag{3.7}$$

where

N_i is the number of moles of monomer i in the reactor
$F_{i,\mathrm{in}}$ are molar flow rate of monomer i into the reactor
V is the reaction volume in the reactor
V_{out} is the total volumetric flow rate of all species out of the reactor
R_{p_i} is the net rate of disappearance of monomer i by reaction

Reaction Volume. Since the density of a polymer is usually significantly greater than that of its monomer, the reaction volume V decreases with conversion for isothermal polymerization in a batch reactor. This shrinkage must also be taken into account in semi-batch and continuous operations. Neglecting volume change on mixing polymer and monomers (thermodynamic data are most often not available and deviation from ideality is often not great) the change in reaction volume (V) may be calculated by using (assuming V is the equilibrium volume):

$$\begin{aligned} \mathrm{d}V/\mathrm{d}t &= V_{\mathrm{in}} - V_{\mathrm{out}} - \text{shrinkage rate} \\ &= V_{\mathrm{s,in}} + \sum_{i=1}^{n} F_{i,\mathrm{in}} M_{\mathrm{m}i}/\varrho_{\mathrm{m}_i} \\ &\quad - \sum_{i=1}^{n} R_{\mathrm{p_i}} M_{\mathrm{m}i} \left(\frac{1}{\varrho_{\mathrm{m}_i}} - \frac{1}{\varrho_{\mathrm{p}}} \right) V - V_{\mathrm{out}} \end{aligned} \quad (3.8)$$

where n is the number of monomer types, $V_{\mathrm{s,in}}$ is the volumetric flow rate of inert solvent into the reactor, $M_{\mathrm{m}i}$ is the molecular mass of monomer i, ϱ_{m_i} is the density of monomer i, ϱ_{p} is the density of polymer produced instantaneously.

Polymer Balances. With a batch reactor, where there is no inflow and outflow of polymer from the reactor, the total amount of polymer formed and its composition can be obtained directly from the monomer balances. However, with semi-batch and continuous operation, additional balances are required and these follow

$$\mathrm{d}P_i/\mathrm{d}t = F_{\mathrm{p}i,\mathrm{in}} - (P_{\mathrm{i}}/V)\, V_{\mathrm{out}} + R_{\mathrm{p_i}} V \quad (3.9)$$

where P_i is the number of moles of monomer i chemically bound in the polymer "in the reactor", $F_{\mathrm{p}i,\mathrm{in}}$ is the molar flow rate of monomer i bound in the polymer flowing into the reactor.

Additional Ingredient Balances. In order to calculate R_{p_i} for free-radical systems, the total polymer radical concentration and, therefore, initiator concentration are required. In addition, balances for the chain-transfer agent (for molecular mass calculations) and for the solvent in solution polymerizations are required. These balances follow:

$$\mathrm{d}N_{\mathrm{I}i}/\mathrm{d}t = F_{\mathrm{I}i,\mathrm{in}} - (N_{\mathrm{I}i}/V)\, V_{\mathrm{out}} - R_{\mathrm{I}i} V \quad (3.10)$$

$$dV_{\mathrm{s}}/\mathrm{d}t = V_{\mathrm{s,in}} - (V_{\mathrm{s}}/V)\, V_{\mathrm{out}} \quad (3.11)$$

$$dN_{\mathrm{T}}/\mathrm{d}t = F_{\mathrm{T,in}} - (N_{\mathrm{T}}/V)\, V_{\mathrm{out}} - R_{\mathrm{T}} V \quad (3.12)$$

where $N_{\mathrm{I}i}$ is the number of moles of initiator of type i in the reactor, $F_{\mathrm{I}i,\mathrm{in}}$ is the molar flow rate of initiator i into the reactor, $R_{\mathrm{I}i}$ is the consumption rate of initiator i by reaction, V_{s} is the volume of inert solvent in the reactor, N_{T} is the number of moles of chain-transfer agent (CTA) in the reactor, $F_{\mathrm{T,in}}$ is the molar flow rate of CTA into the reactor, and R_{T} is the consumption rate of CTA by reaction.

It is convenient to sum the monomer balance equation (Eq. 3.7) over n, the number of monomer types to give

$$\mathrm{d}N_{\mathrm{M}}/\mathrm{d}t = F_{\mathrm{in}} - (N_{\mathrm{M}}/V)\, V_{\mathrm{out}} - R_{\mathrm{p}} V \quad (3.7a)$$

where N_{M} is the total number of moles of monomer in the reactor, F_{in} is the total molar flow rate of monomer to the reactor, R_{p} is the total molar consumption rate of monomer by reaction.

3.3.1.1. Rates of Reaction and Copolymer Composition

With application of the pseudo-kinetic rate constant method, R_{p} can be expressed as

$$R_{\mathrm{p}} = K_{\mathrm{p}}\, [\mathrm{M}]\, [\mathrm{P}^*] \quad (3.13)$$

where

$$[\mathrm{M}] = N_{\mathrm{M}}/V = \sum_{i=1}^{n} [\mathrm{M}_i] \quad (3.13a)$$

and $[\mathrm{M}_i]$ is the concentration of monomer of type i in the reactor.

When the terminal model [356] for copolymerization is valid

$$[\mathrm{P}^*] = \sum_{i=1}^{n} [\mathrm{P}_i^*] \tag{3.13b}$$

where $[\mathrm{P}_i^*]$ is the concentration of active centers of type i in the reactor and

$$K_\mathrm{p} = \sum_{i=1}^{n} \sum_{j=1}^{n} K_{\mathrm{p_{ij}}} \varphi_i^* f_j \tag{3.13c}$$

where φ_i^* is the number fraction of active centers of type i in the reactor, and f_j is the mole fraction of monomer of type j in the reactor.

When the penultimate model [356] for copolymerization is valid

$$[\mathrm{P}^*] = \sum_{ij}^{n} [\mathrm{P}_{ij}^*] \tag{3.13d}$$

and

$$K_\mathrm{p} = \sum_{ijk}^{n} K_{\mathrm{p}_{ijk}} \varphi_{ij}^* f_k \tag{3.13e}$$

The fraction of active centers of type i (φ_i^*) can be found by using the stationary state hypothesis (SSH). Model development will continue assuming that the terminal model for copolymerization is valid. The φ_i^* may be found by using

$$\sum_{\substack{j=1 \\ j\neq i}}^{n} R_{\mathrm{p}_{ji}} = \sum_{\substack{j=1 \\ j\neq i}}^{n} R_{\mathrm{p}_{ij}} \tag{3.14a}$$

with $i = 1, \ldots n$ and where $R_{\mathrm{p}_{ij}}$ is the consumption rate of monomer j adding to the active center i.

For anionic, cationic, and anionic coordination polymerization, the estimation of the total number of active centers is not always straight forward, and this quantity is sometimes used as an adjustable parameter. For free-radical polymerization, a balance between radical generation rate and bimolecular termination rates provides the following with use of the SSH

$$[\mathrm{R}^\cdot] = \left(R_\mathrm{I}/\bar{K}_\mathrm{tN}\right)^{1/2} \tag{3.14b}$$

where $[\mathrm{R}^\bullet]$ is the total concentration of polymeric radicals in the reactor, R_I is the generation rate of polymeric radicals of chain length unity, and $\bar{K}_\mathrm{tN}$ is the number-average bimolecular termination constant. When termination by combination and disproportionation are both significant

$$\bar{K}_\mathrm{tN} = \bar{K}_\mathrm{tcN} + \bar{K}_\mathrm{tdN} \tag{3.14c}$$

For chemically controlled bimolecular termination, pseudo-kinetic rate constants for $\bar{K}_\mathrm{tcN}$ and $\bar{K}_\mathrm{tdN}$ may be found in [355–357]. Details concerning the definitions and use of $\bar{K}_\mathrm{tN}$, $\bar{K}_\mathrm{tW}$, $\bar{K}_\mathrm{tZ}$, may be found elsewhere [358], [359]. The definition of $\bar{K}_\mathrm{tN}$ follows:

$$\bar{K}_\mathrm{tN} = \sum_{r=1}^{\infty} \sum_{s=1}^{\infty} K_\mathrm{t}\,(r,s)\,\psi\,(r)\,\psi\,(s) \tag{3.14d}$$

where $K_\mathrm{t}\,(r, s)$ is an arbitrary bimolecular termination constant distribution for reaction of polymeric radicals of chain length r and s and $\psi\,(r)$ and $\psi\,(s)$ are the number fractions of polymeric radicals of chain length r and s. Note that $\bar{K}_\mathrm{tN}$ can be used to calculate R_p and $\bar{M}_\mathrm{N}$ but if used to calculate higher molecular mass averages they would be underestimated if a significant number of polymer chains are formed by bimolecular termination reactions [358].

Realistic calculations of [R] using Equation (3.14 b) requires that the SSH be valid and that diffusion-controlled bimolecular termination be accounted for. The first direct experimental test by ESR of the validity of the SSH for bulk polymerization of methyl methacrylate (MMA) (where linear polymer chains are produced) and of MMA – ethylene glycol dimethacrylate (EGDMA) (where chains with long branches and polymeric networks are formed) has shown that SSH is valid for bulk MMA polymerization, but is not valid when substantial crosslinking occurs [360]. Coyle et al [361] have confirmed the validity of SSH for bulk polymerization of MMA using numerical solutions of the full set of kinetic equations. Attempts to model diffusion-controlled bimolecular termination is considered later when discussing the polymerization of MMA (see page 53) which is considered the model system because of its extreme Trommsdorff – Norrish effect. At very high monomer conversions, when the polymerization temperature is below the glass transition temperature of the polymer being synthesized, the initiator efficiency and propagation constant

both begin to fall dramatically, and these effects should be properly accounted for. These effects will also be considered in detail later when MMA polymerization is discussed. The modeling of diffusion-controlled bimolecular termination, propagation, and the cage effect on initiator efficiency is not entirely clear, and much research must be done before these topics may be considered standard engineering practice.

The polymerization rates for individual monomer type j can be calculated from

$$R_{\mathrm{p}j} = \left(\sum_{i=1}^{n} K_{\mathrm{p}_{ij}} \varphi_i^* f_j \right) [\mathrm{M}]\,[\mathrm{P}^*] \tag{3.14e}$$

with $j = 1, \ldots n$.

The mole fraction of monomer of type j in copolymer produced instantaneously is given by

$$F_j = R_{\mathrm{p}_j} / R_{\mathrm{p}} \tag{3.14f}$$

Monomer sequence length distributions may be calculated by using equations given in [356].

3.3.1.2. Molecular Masses, Long-Chain Branching, and Cross-Linking

Linear Copolymer Chains. For chain lengths greater than about 50 and when the terminal model for copolymerization is valid, STOCKMAYER's bivariate weight chain length distribution may be used to calculate the composition and chain length of binary copolymer produced instantaneously [356], [362]. The bivariate distribution of the accumulated polymer is readily calculated by integrating the instantaneous distribution using weighting factors based on instantaneous rates of polymer production. Unfortunately, an analytical function for a multidimensional distribution (involving three or more monomer types) has yet to be derived. However, part of this problem has already been solved. In the limit of large chain lengths, the copolymer composition of chains produced instantaneously may be assumed to be independent of chain length, and therefore, the instantaneous bivariate weight chain length distribution is that given by the same expression as for homopolymerization with all of the chains having the same composition F_i. For more details, see Section 2.3.1 and [356].

Long-Chain Branching and Cross-Linking. The production of long branches and cross-links requires that so-called dead polymer chains take part in branching reactions to produce tri- and tetrafunctional branch points via transfer to polymer and by addition of polymer radical centers to polymer double bonds. The mechanisms of anionic, cationic, and anionic coordination polymerization invariably produce linear polymer chains. There may be a few exceptions, but these will not be considered.

Pseudo-kinetic rate constants for transfer to polymer and polymer radical addition to pendant double bonds may be defined as [355], [357], [363–365]

$$K_{\mathrm{fp}} = \sum_{ij}^{n} K_{\mathrm{fp}_{ij}} \varphi_i \bar{F}_j \tag{3.15}$$

$$K_{\mathrm{p}}^* = \sum_{ij}^{n} K_{\mathrm{p}_{ij}}^* \varphi_i \bar{F}_j \tag{3.16}$$

when the terminal model is valid; where $\bar{F}_j$ is the mole fraction of monomer j chemically bound in the accumulated polymer. When a significant number of labile atoms have been abstracted and when a significant number of double bonds have been consumed, Equations (3.15) and (3.16) should be modified to account for this [363], [364].

When polymer chains that are normally inert to further reaction undergo long-chain branching reactions, the instantaneous MWD is no longer a permanent quantity. Therefore, the method of moments should be used to calculate the molecular mass averages. For details on the use of the method of moments for the calculation of sol molecular mass averages before and after the gelation point and other methods for calculating sol – gel fraction and cross-linking density, see [363–365].

3.3.2. Examples of Free-Radical Polymerization

3.3.2.1. Homopolymerization – Linear Chains

The modeling techniques described in Section 3.3.1 are illustrated with actual monomer systems and experimental kinetic data. The simplest modeling examples (homopolymerization

producing linear chains) are considered first, beginning with the thermal bulk polymerization of styrene, which is relatively easy to model and the modeling has been most successful in a variety of applications.

Bulk Thermal Polymerization of Styrene ($T > 100\,°C$). This system is comparatively easy to model for the following reasons:

1) The Mayo mechanism for thermal initiation of radicals is valid [366–368]
2) The polystyrene chains are linear
3) The Trommsdorff – Norrish effect (see Section 2.2.1.2), although significantly affecting the polymerization rate, has at most a minor effect on molecular mass development because most of the polymer chains are produced by chain transfer to the Diels – Alder intermediate [366].

The size of the polymeric radicals (radical centers are exclusively on chain ends) depends on temperature and monomer concentration (or conversion), and the molecular mass distribution of the accumulated polymer differs little from that of the polymeric radicals. In general, the self-diffusion coefficients of polymer radicals should depend on the size of the macroradical, the concentration and MWD of the accumulated polymer, and temperature. The size of the macroradical is of greater importance than the MWD of the accumulated polymer [369], [370].

An empirical correlation of the bimolecular termination constant with polymerization temperature and monomer conversion should provide a model which is applicable over a range of process conditions (batch and continuous reactor operation, temperature programming, etc). Another important factor, revealed in the work of Kirchner and Riederle [367], is that reactions involved in thermal initiation do not become diffusion controlled at monomer conversions as high as 97 %. The first effective model for the bulk thermal polymerization of styrene was developed by Hui and Hamielec [371] and later extended to higher temperatures ($T < 230\,°C$) [372] and shown to be valid for a continuous stirred-tank reactor up to 280 °C [373]. This model has been evaluated by many workers over a wide range of reactor type and operational conditions. These include:

1) Wu et al. [374] used the model for a theoretical/experimental optimization study employing temperature programming in a batch reactor with highly successful results.
2) Kirchner et al. [375] applied the model to a CSTR and obtained accurate predictions.
3) Tien et al. [375] applied the model to a tubular reactor with internal mixers.
4) DIERS [376], [377] (Design Institute for Emergency Relief Systems) a consortium of chemical and insurance companies financed the design and construction of a unique adiabatic reactor system (see Fig. 26) for the measurement of temperature and pressure/time variations during adiabatic runaway exothermic reactions. They measured responses for the adiabatic thermal polymerization of styrene (Fig. 27 and 28) and compared them with those predicted by the Hui – Hamielec polystyrene model and found excellent agreement.

Figure 28. VSP Pressure – time response for the adiabatic thermal polymerization of styrene (80 wt % styrene and 20 wt % ethylbenzene) compared with the predictions of the H–H polystyrene model with temperature-dependent heat of reaction [377]
(kPa = psi × 6.89)
a) Prediction: total pressure (maximum 360 psig);
b) Prediction: partial vapor pressure (maximum 312 psig)
• Experimental data

The pressure calculation required the use of the Flory – Huggins equation (Eq. 3.17). These evaluations under extreme conditions confirm that the H–H model for the thermal polymerization of styrene is indeed useful in a variety of applications. These kinds of evaluations, which, however, have not been carried out for any other polymerization model, should be considered standard tests for polymerization models before they are accepted for general engineering use.

Figure 29. Thermal polymerization of *p*-methylstyrene: molecular mass development followed by GPC and light scattering (LALLS). Deviation for $\overline{M}_W$ between GPC and LALLS suggests that LCB frequency is increasing with monomer conversion. Solid curves are model predictions neglecting chain transfer to polymer [378].

A monomer which polymerizes thermally and almost identically to styrene is 4-methylstyrene [378]. With the latter monomer some long-chain branching occurs due to chain transfer to methyl hydrogens in the polymer backbone. An effective experimental technique to confirm the presence of long branches [378] is to measure $\bar{M}_W$ by light scattering and by GPC at different monomer conversions in isothermal batch polymerization. The molecular mass calibration curve for GPC should be constructed using linear poly(4-methylstyrene). At low conversions, where chains are almost all linear, $\bar{M}_W$ by light scattering and GPC should agree. However, at high conversions where long-chain branching should be significant (if it is present at all), $\bar{M}_W$ by light scattering should be greater than that by GPC and the difference should increase with increasing monomer conversion. Figure 29 shows an example of this behavior. Long-chain branching in poly(4-methylstyrene) has been satisfactorily modeled by accounting for chain transfer to polymer and using light scattering $\bar{M}_W$'s which should be valid for branched homopolymer [378]. Another effective procedure to verify the presence or absence of long-chain branching is to add a previously synthesized narrow-MWD sample of the polymer that is to be synthesized to the monomer solution and then polymerize. The newly synthesized polymer is then com-

pletely separated from the old polymer by GPC. If the GPC response for the added polymer shifts towards larger radii of gyration (hydrodynamic volume) this is evidence for long-chain branching [379].

Bulk polymerization of methyl methacrylate (MMA) with free-radical initiator is the model monomer system for the investigation of diffusion-controlled bimolecular termination and propagation and the decrease in initiator efficiency at high monomer conversions (cage effect). It has the largest Trommsdorff – Norrish effect because most of the polymer chains are produced by bimolecular termination and the higher average molecular masses ($\bar{M}_W$, $\bar{M}_Z$, $\bar{M}_{Z+1}$) increase dramatically in the absence of a chain-transfer agent. The MWD shifts to higher molecular masses and sometimes becomes bimodal [380]. GPC detector responses, multiplied by monomer conversion so that the total area under the detector response is proportional to the amount of polymer in the batch reactor, are shown in Figure 30. At the monomer conversion where the number of physical chain entanglement points becomes significant a spike of high molecular mass polymer is produced. Thereafter, polymer with lower molecular masses is no longer produced. The instantaneous MWD has clearly shifted towards higher molecular mass (higher molecular mass polymer has a lower GPC retention volume or retention time). MMA is generally polymerized below the glass transition temperature of PMMA (ca. 110 °C) and as a consequence the initiator efficiency and propagation constant decrease dramatically at high monomer conversions ($\sim$ 80 %) due to restrictions on diffusion rates during the glassy-state transition because of appreciable loss in free volume. There is also evidence that during the rapid autoacceleration in polymerization rate (due to large increase in polymer radical concentration [360]) radicals become frozen in the glassy-state [358]. Radical pairs which form in the cage may become frozen after a few monomer additions because of monomer starvation. This homopolymerization is difficult to model. Nevertheless, there have been many serious attempts to model this system [381–392]. More recent research has focused on predicting the fall in initiator efficiency and propagation constant at high conversion and on the use of a simple chain-length-dependent model for bimolecular termination. This work has been summarized in a recent article by Adams et al. [393]. The first important models [381–383] for MMA polymerization were carefully evaluated [384] using comprehensive rate and molecular mass data involving three different initiator types measured by Röhm. The Marten – Hamielec model was found to better satisfy the specifications for a polymer reactor model that can be used to optimize commercial production systems. It was pointed out however, that further work should be done to investigate the applicability of the model to systems that have been prepolymerized and also polymerized nonisothermally (perhaps with temperature programming or adiabatically) and for systems with mixed initiators. Panke [394] has more recently shown that when using prepolymer, simulations are better when the parameter n is changed from 1.75 to 0.5 in the M–H model. From a fundamental point of view the M–H model has several weaknesses which should be pointed out. Chain-length dependence of bimolecular termination is accounted for in an overly simplified manner. The weight-average molecular mass of the accumulated polymer does reflect the change in the size of the macroradicals but in a dampened fashion. For example, a sudden change in the size of the macroradicals would not be felt soon enough, particularly when a substantial amount of dead polymer has accumulated. This model effectively uses one termination constant (the number-average termination constant [358]). It can therefore predict polymerization rate and number-average molecular mass, but invariably underestimates $\bar{M}_W$ and higher molecular mass averages. The M–H model as well as most others have assumed that K_p becomes diffusion controlled while the initiator efficiency f remains constant. It has long been known that the initiator efficiency falls at high conversions [395–398]. To separate the product $f^{\frac{1}{2}}K_p$ which appears in the rate expression, accurate molecular mass data at high conversions are required. This has not been possible to date, because of the difficulty of measuring $\bar{M}_N$ and $\bar{M}_W$ for the very high molecular mass PMMA produced during the autoacceleration of reaction rate. For all of the models for which f was taken to be independent of monomer conversion, the observed decrease in K_p is actually

the decrease in $f^{\frac{1}{2}}K_p$. The change in K_p at very high monomer conversions can be measured by ESR [360], [399] and of course this would permit the estimate f from the product $f^{\frac{1}{2}}K_p$. Another factor which has been completely overlooked is that during the autoacceleration when approaching the glassy-state transition, the actual volume of the polymerizing mixture may be significantly greater than the local equilibrium volume. This is largely responsible for the fact that the limiting conversion depends on the initiator concentration at high initiator and radical concentration levels [400–402].

Figure 30. GPC chromatograms showing molecular mass development due to the Trommsdorff–Norrish effect for the isothermal bulk free-radical polymerization of methyl methacrylate in a batch reactor
Parameter x denotes monomer conversion ($T = 70\,°C$, [AIBN] = 0.3 wt %) [380]

During the autoacceleration in polymerization rate which accompanies diffusion-controlled bimolecular termination, it is difficult to maintain isothermal conditions. The use of large ampoule reactors with inadequate surface-to-volume ratios for heat transfer has been recently criticized [403], [404]. The use of ampoule reactors (3 – 5 mm diameter) is recommended for kinetic investigations of the Trommsdorf – Norrish effect [404].

3.3.2.2. Copolymerization – Linear Chains

The terminal model has been very useful for predicting the average compositions of binary copolymers synthesized with vinyl monomers having a wide variety of structures and range of reactivities. The terminal model has not been as successful in the prediction of comonomer sequence length distributions [405], [406] and the propagation rate [407–413]. Model discrimination has been based on the use of measurement techniques which provide estimates of the elementary overall (or pseudo-kinetic) rate constants K_p and $\bar{K}_{tN}$. These include rotating sector [407–409], spatially intermittent polymerization (SIP) reactor [414], and pulsed-laser techniques [411–413]. ESR measurements [410] have also been used to show the existence of penultimate effects. Most of these studies considered the binary copolymerization of styrene and methyl methacrylate; however, other monomer pairs have been investigated including: styrene – acrylonitrile [408] and styrene with a series of alkyl methacrylates [408], [415]. The use of the pulsed-laser technique has a serious limitation when applied to copolymerization. One must measure the MWD by GPC and the potential errors are several and potentially serious. For example, there is inevitable statistical broadening of composition distribution for short chains and the uncertainty that the concept of universal molecular mass calibration is valid. Nonuniform composition of chains in the detector cell makes the conversion of detector response to polymer solute concentration uncertain and in addition the errors due to deviation from the universal calibration curve may be significant.

Most of the serious attempts to model binary copolymerizations from an industrial perspective (accounting for diffusion-controlled bimolecular termination and propagation and for the fall in initiator efficiency at high conversions) have employed the terminal model and the pseudo-kinetic rate constant method [355], [357], [416–423]. There have been some recent attempts to employ the penultimate model in this regard [424], [425]. It should be stressed that whether terminal or penultimate models are used appropriate pseudo-kinetic rate constants can be defined for calculating rates of polymerization and molecular mass distribution [356].

3.3.2.3. Copolymerization – Long-Chain Branching

The few serious attempts to model polymerization rate and molecular mass development have employed the pseudo-kinetic rate constant method with the method of moments [355], [357], [363–365], [418], [419], [422]. The method of instantaneous MWD, which is such a powerful method for calculating the full MWD for linear multicomponent polymers is not useful when dead polymer chains can be reactivated during formation of long-chain branches. The instantaneous MWD is no longer a permanent quantity but loses some of its chains, which become branched during the course of polymerization. It should be noted here that the pseudo-kinetic rate constant method is equally valid for the modeling of linear and branched copolymer chain synthesis. The most common analytical technique for the measurement of long-chain branching frequency (average number of branches per polymer molecule or per 1000 backbone carbon atoms) is GPC with a dual detector system (mass concentration detector plus either a viscometer or light scattering photometer as detector in series) or GPC with off-line viscometry [426].

3.3.3. Polymerization Processes

3.3.3.1. Solution Polymerization

3.3.3.1.1. Polymer Soluble in Monomer

Kinetics. A polymerization in which the polymer being synthesized is soluble in its monomer may be called a bulk or mass as well as a solution polymerization. A full description of the polymerization kinetics and modeling techniques can be found in Section 2.2.1 and Section 3.3.2.

Polymerization Processes. The main technical problems associated with solution polymerization are heat removal, recovery of residual monomer and solvent, and the manipulation of highly viscous solutions and melts. It is well known that the ratio of cooling surface area to volume of reacting mixture decreases as the reactor volume increases. Length-to-diameter ratios for reactors are usually < 2 to achieve acceptable mixing. When jacket cooling is no longer sufficient to maintain isothermal polymerization, additional modes of heat transfer must be used, as shown in Figure 31. Internal cooling coils are often not practical because they tend to interfere with stirring. External tubular coolers can, in principle, provide a very large heat-transfer area, but they may have very large pumping requirements in the case of highly viscous solutions. Reflux cooling removes the heat of polymerization by evaporation of solvent and/or monomer; the condensed vapor is recycled to the reacting mass. Condensers may be as large as necessary, with the limiting factor usually the amount of vapor that can be treated without causing intense foaming or spattering of the polymer solution. Remixing of the condensed liquid with the more viscous reacting mass may also be difficult.

3.3.3.1.2. Addition of a Solvent in which both Monomer and Polymer are Miscible

The addition of a solvent in which both monomer and polymer are miscible lowers the viscosity of the reacting mass, thereby improving its flow and heat-transfer characteristics. As a result, and depending upon the nature and con-centration of the solvent, the Trommsdorff – Norrish effect can be either completely suppressed or significantly reduced. Use of solvent can be especially beneficial when evaporative cooling is used. In choosing a solvent, it is important to take into account the possibility of chain transfer to solvent with a concomitant reduction in polymer molecular mass. Removal of solvent and residual (unreacted) monomer from the highly viscous polymer solution requires very high surface areas to permit rapid devolatilization at the moderate temperatures required to minimize polymerization and degradation of chains during devolatilization to reduce off-spec polymer. Figure 32 illustrates possible designs of devolatilizers. One of these, the vacuum degasser, incorporating a type of spray device [427], operates adiabatically, which means that the heat for evaporation is supplied by the solution itself. In contrast, a degasser in series with a tubular heat exchanger causes some of the monomer/solvent to

Figure 31. Alternative methods of heat removal for polymerization conducted in a stirred reactor
A) Internal cooling coils; B) External cooler; C) Reflux cooling

evaporate during passage through the heat exchanger. This evaporation accelerates the flow of product, thereby increasing the heat-transfer rate [428]. Twin-screw extruders with one or more vapor outlets that can be connected to a vacuum source are also utilized for the removal of monomer and solvent [429], [430]. Intermeshing and self-cleaning screws provide continuous renewal of the evaporating surface. The use of thin-film evaporators with rotating wiper blades has also been suggested [431].

Given stable operation of the devolatilizer, solution polymerization can be carried out in a continuous stirred-tank reactor [432], [433]. Conversion is normally lower than with tower processes, however, requiring large amounts of monomer/solvent to be recovered and recycled to the reactor. Special attention must therefore be paid to the buildup of impurities (e.g., inhibitors, chain-transfer agents) over time by using appropriate purge streams. Problems with processes involving step-growth polymerization are discussed in Section 3.2.

3.3.3.1.3. Polymer – Polymer Demixing during Polymerization

Polymer – polymer demixing is especially important in the production of thermoplastics whose application characteristics are enhanced by the presence of dispersed domains containing an elastomer. Generally, the thermodynamics are unfavorable for complete miscibility between different types of polymers. For a system polymer A – polymer B – solvent, the following generalizations are usually applicable [434], [435]: dilution with solvent and, in most cases, an increase in temperature increases the compatibility; increasing the molecular masses of the polymers has the opposite effect. Except in the case of high dilution, incompatibility in solution is the rule for pairs of polymers, even when the solvent is a good solvent for both polymer types.

Systems such as polymer A – polymer B – block or graft copolymer AB can be regarded as a polymeric oil-in-oil emulsion in which the copolymer functions as an emulsifying agent [436–439]. Such systems arise, for example, in the manufacture of high-impact polystyrene (HIPS), or in the preparation of ABS (acrylonitrile – butadiene – styrene) by solution polymerization. In the simplest case, ca. 5 – 10 % polybutadiene is dissolved in monomeric styrene to give a homogeneous solution suitable for polymerization. The polystyrene synthesized is incompatible with the polybutadiene present, causing phase separation even at very low monomer conversion and producing a polybutadiene – styrene continuous phase and a polystyrene – styrene disperse phase. Simultaneously, graft polymerization produces polystyrene branches on polybutadiene backbone. The graft copolymer serves as an emulsifier, accumulating at the interface and stabilizing the oil-in-oil emulsion.

With increasing conversion, the volume fraction of the polystyrene phase (which is initially small) increases considerably due to formation of additional polystyrene which absorbs styrene monomer. Finally, often at a phase-volume ratio of about unity, a phase reversal occurs, with the rubber phase now the disperse phase, and the

Figure 32. Options for removing residual monomer and solvent
A) Strand degasser; B) Tubular evaporator; C) Degassing extruder; D) Thin-film evaporator

polystyrene phase the continuous phase. Agitation is essential for the completion of phase reversal, since rapid approach to equilibrium with respect to transfer of monomer/polymer must be attained in a highly viscous medium. A common result of inadequate agitation is the interpenetration of two continuous phases [438], [440–442].

Phase reversal can also lead to various types of emulsions; e.g., polystyrene – styrene droplets can be occluded within the rubber particles of the disperse phase. This is actually desirable as it increases the volume fraction of the disperse rubber phase. A reinforcing effect is observed, with the resulting HIPS having higher impact strength for a given mass of rubber in comparison with materials prepared by emulsion grafting, in which occluded polystyrene is not formed [443], [444]. Rather than rely on in situ formation of grafted rubber, it is also possible from the outset to utilize block copolymers of styrene and butadiene as an additive in the recipe. The desired particle size distribution and morphology of the rubber particles in HIPS is then achieved by varying the intensity of agitation, the viscosities of the disperse and continuous phases, the graft activity of the primary radicals of the initiator, the molecular mass of the continuous phase, and the mass fraction and molecular mass of the blocks in the diblock copolymer [445–454].

Figure 33 provides examples of the morphology of these rubber-modified polystyrene systems. Morphologies of commercial significance are essentially limited to cell and capsule structures, since the other morphologies shown generally provide lower impact strength.

3.3.3.2. Precipitation Polymerization

The term precipitation polymerization refers to processes in which the initial ingredients of a recipe are soluble, giving a homogeneous solution, but the synthesized polymer precipitates during the course of polymerization. The precipitated polymer is generally swollen with monomer and with nonsolvent if present. To ensure convenient handling the disperse phase must be finely divided. This is achieved by effective agitation, and a protective colloid (steric stabilizer) is often used. The associated problems are similar to those with HIPS manufacture.

3.3.3.2.1. Polymer Insoluble in its Monomer

Polymers that are insoluble in their monomers include poly(vinyl chloride) and other polymers derived from halo or pseudohalo-substituted ethylenes such as vinyl bromide, vinylidene chloride, trifluoroethylene, and acrylonitrile. Polyethylene also falls into this category, at least when produced under moderately high pressure. For the system vinyl chloride – poly(vinyl chloride), for example, virtually no polymer dissolves in the monomer in the temperature range 30 – 60 °C. Solubility of the monomer in the polymer is described well by the simplified

Figure 33. Possible morphologies for rubber particles in impact resistant polystyrene [454]
Length of the scale bar: 1 μm

Flory – Huggins equation (3.17) [435, p. 511], [455–457]:

$$\ln\left(\frac{p}{p_0}\right) = \ln\,(1-\varphi_{\mathrm{P}}) + \varphi_{\mathrm{P}} + \chi\varphi_{\mathrm{p}}^2 \qquad (3.17)$$

where

p_0 is the vapor pressure of pure vinyl chloride
p is the partial pressure of vinyl chloride
φ_{p} is the volume fraction of poly(vinyl chloride)
χ is the polymer – solvent interaction parameter.

According to [457], deviations from Equation (3.17) are expected at low vapor pressures. The conversion – time curves for the bulk polymerization of such monomer – polymer systems all display rate increases with increasing conversion. This phenomenon has been especially thoroughly investigated for the bulk polymerization of vinyl chloride. Its cause may be interpreted as follows: even at very low conversion, poly(vinyl chloride) precipitates, forming a monomer-swollen polymer-rich phase. Initiator is partitioned between the phases, and thus radical generation and polymerization occur in both phases. The bimolecular termination rate is diffusion controlled in the polymer-rich phase and hence the concentration of radicals is higher in this phase. Even though the monomer concentration is lower in the polymer-rich phase, the specific polymerization rate R_{p} is higher. In addition, the volume of the polymer-rich phase grows at the expense of the monomer-rich phase with increasing monomer conversion. This explains the autoacceleration in rate as monomer conversion increases.

Figure 34. Time – conversion curve for the bulk polymerization of vinyl chloride [459]

[I]: • 0.78×10^{-3} ; ■ 1.57×10^{-3} ; △ 3.38×10^{-3} ; × 5.50×10^{-3} mol/mol vinyl chloride

Talamini has suggested that such a reaction may be described in terms of two homogeneous polymerizations occurring in parallel, with rapid monomer transfer from the monomer-rich to the polymer-rich phase [458], [459]. Assuming that the monomer/polymer mass ratio in the polymer-rich phase is independent of conversion or time, and that the ratio of the specific polymerization rates in the two phases re-

mains constant (Talamini suggests a ratio of ca. 19 at 50 °C), then the observed conversion – time curve can be described well up to ca. 70 % conversion, as shown in Figure 34. However, Talamini's model fails at higher conversions because the monomer-rich phase disappears, and polymerization now occurs only in the remaining polymer-rich phase, with a monomer concentration which decreases with increasing reaction time. Several authors have offered extensions and modifications of the original Talamini model [460–468].

An industrial example of precipitation polymerization is the Pechiney – Saint Gobain two-stage bulk polymerization process [469–472], or the more popular suspension polymerization where poly(vinyl chloride) precipitates in the monomer droplets (→ Poly(Vinyl Chloride)). Precipitation polymerization also encompasses what has been called "gas-phase" polymerization, a process in which polymer particles form within a monomer vapor. Such polymerization does not actually occur in the gas phase, however, because the catalyst resides either within or on the surface of existing polymer particles, and a significant amount of monomer is dissolved in the polymer. The actual site of polymerization is thus within the polymer particle, to which a continuous supply of monomer flows from the gaseous phase. Commercial examples of gas-phase processes include the Union Carbide Unipol process [473–476] and the BASF process [477–481] for low-pressure polymerization of ethylene and propylene (→ Polyolefins, Chap. 1.5.3., → Polyolefins, Chap. 2.5.6.). Figure 35 shows a schematic of the Unipol process in which polyethylene powder is produced using ethylene as a fluidizing gas in a fluidized-bed reactor that contains a modified chromium catalyst. A high-density polyethylene (HDPE) which has a very broad molecular mass distribution and linear chains is produced. Copolymerization of ethylene with propene, 1-butene, and 1-hexene gives products with a controlled amount of short-chain branching and lower polymer density (LLDPE) [482]. The densities of LLDPE are between those of HDPE and LDPE made in the high-pressure free-radical processes.

Polymer – monomer – precipitant systems employ a nonsolvent for the polymer, while the precipitant is miscible with the monomer. The most important example is probably the so-called slurry process for the manufacture of high-density polyethylene (HDPE), isotactic polypropylene, and their copolymers (→ Polyolefins, Chap. 1.5.2., → Polyolefins, Chap. 2.5.1.) Ziegler – Natta (transition-metal catalysts) are used in these processes. Polymerization is often conducted continuously in a train of well-mixed reactors in the presence of a nonsolvent hydrocarbon, usually a C_{6-7} hydrocarbon, at ca. 50 – 100 °C and 5 – 30 bar. Polymer chains grow on suspended, very fine catalyst particles. Soluble, homogeneous catalysts of the Ziegler – Natta type are also known and have gained commerical interest. The productivity of modern catalysts is so high (greater than 100 kg polyethylene per gram transition metal) that subsequent removal of the catalyst from the polymer product is not required. An overview of earlier developments with respect to these catalysts is provided in [483].

Stirred-tank reactors are generally used for this process, often linked in series to give a cascade or train [484], [485]. A simplified schematic of the Hoechst process is shown in Figure 36. Similar slurry processes also exist for polypropylene [486] and copolymers

Figure 36. Schematic of the Hoechst slurry-process for HPDE [484]
a) Mixing vessels; b) Reactor; c) Postreactor; d) Centrifuge; e) Stripper; f) Dryer; g) Silo for HDPE powder

based on ethylene – propene (EPM) and ethylene – propene – diene (EPDM) mixtures. Acrylonitrile, sometimes together with a comonomer, can be polymerized in aqueous phase using a redox system such as $K_2S_2O_8$–$Na_2S_2O_5$ or H_2O_2–Fe^{2+} [487]. The polymer precipitates as a fine powder, which is then filtered, washed, and dried. Dissolution of the polymer powder in dimethylformamide produces a spinning solution that can be used to produce polyacrylonitrile fibers. This process has been conducted in a continuous manner [488]. One of the first commercial precipitation polymerizations was the belt conveyor process for polyisobutylene developed by BASF (Fig. 37; see also → Polyolefins, Chap. 4.2.4.). Equal amounts of isobutene and ethylene are first mixed and then deposited in the liquid state on a circulating steel belt. A second inlet is used to add a solution of BF_3 in ethylene. Cationic polymerization occurs very rapidly, and the heat of polymerization is dissipated by the evaporation of ethylene. Thus, ethylene functions here not only as a precipitant but also as a medium for evaporative cooling. The resulting gaseous ethylene is purified, liquefied, and recycled.

A similar process is used by Exxon for the synthesis of butyl rubber [489]. In this case, isoprene serves as the comonomer and methyl chloride takes the place of ethylene. Polymerization is carried out in a continuous stirred-tank reactor. Residual monomer and diluent are removed from the resulting polymer suspension by stripping with hot water.

3.3.3.2.2. Monomer Functioning as Solvent for the Polymer

The Polymer – Monomer – Precipitant System. If the polymer is soluble in its monomer, precipitation polymerization requires the addition of a precipitant that is miscible with the monomer. Polymerization then begins in a solvent – nonsolvent mixture and it ends in a phase consisting only of pure precipitant once conversion of the monomer is complete. Thus, the solubility relationships change during the course of the polymerization, and polymerization may initially occur in a homogeneous manner prior to the onset of precipitation, induced by the enrichment in precipitant that accompanies the consumption of monomer.

Figure 38. Volume-fraction $*\gamma_{\mathrm{prec}}$ (—-) of methanol as a function of conversion for various initial concentrations of monomer $[\mathrm{M}]_0$ [491]
Azeotropic precipitation copolymerization of styrene – acrylonitrile in methanol (– – –), precipitation point determined using cloud-point titration for two different degrees of polymerization

Figure 38 illustrates these relationships, using as an example the copolymerization (in methanol as precipitant) of 40 mol % acrylonitrile and 60 mol % styrene (at the azeotropic composition). The volume fraction $*\gamma_{\mathrm{prec}}$ of methanol in the reaction mixture, defined as

$$*\gamma_{\mathrm{prec}} = \frac{\text{volume of precipitant}}{\text{volume of precipitant} + \text{volume of solvent}} \tag{3.18}$$

is plotted in Figure 38 as a function of conversion for various initial concentrations of monomer $[\mathrm{M}]_0$. The dashed lines represent extrapolations from experimental cloud-point titration data, which give the $*\gamma_{\mathrm{prec}}$ values at which the first polymer fractions precipitate at 65 °C. For an initial concentration $[\mathrm{M}]_0 < 4.1$ mol/L, extremely small conversions suffice to cause precipitation. At high monomer concentrations the polymer initially remains in solution because the volume fraction of methanol required for polymer precipitation has not yet been reached. In such cases, the critical value of $*\gamma_{\mathrm{prec}}$ is exceeded only at higher conversion: the greater $[\mathrm{M}]_0$, the higher the conversion required.

In precipitation polymerization of this type it is especially important to ensure that the polymer precipitates in finely divided form. Among other things this ensures that the particles do not overheat during polymerization. The process has been employed on large scale by BASF [490–492], with batch polymerization occurring in stirred reactors under reflux at 65 °C. Azobisisobutyronitrile was employed as initator, and poly(vinyl pyrrolidone) or poly(vinyl ether) as a protective colloid. The resulting styrene – acrylonitrile copolymer was separated by centrifugation and the recovered methanol was distilled and recycled to the next batch.

Polymer dispersions in nonaqueous media with particle size in the range 0.01 – 10 µm (nonaqueous dispersions, colloids, organosols) have been thoroughly investigated by BARRET and coworkers [493]. BARRET characterizes "dispersion polymerization" as a process in which an insoluble – and thus dispersed – polymer is prepared from a monomer dissolved in an organic diluent to which has been added an amphiphatic block or graft copolymer to serve as a dispersant. However, here this is regarded as a special case of precipitation polymerization in which complete coagulation of polymer particles is prevented and the particle size is controlled.

The key to controlling particle size is the selection of dispersant type. Among the most effective dispersing agents are the so-called amphipathic molecules: block and graft copolymers made up of two polymeric components, only one of which is insoluble in the continuous, diluent-containing phase. Graft copolymers of this type often form during the polymerization as a result of grafting on the dissolved polymer, but it is not absolutely essential that the insoluble portion of the dispersant be identical to or soluble in the disperse phase. In many cases its insolubility in the diluent is sufficient to ensure adequate adsorption on the particle surface. These amphipathic dispersing agents act as steric stabilizers [494].

Figure 39. Steric stabilization of precipitating polymer/monomer particles with the aid of amphipathic block and graft copolymers [495]
A) Schematic representation of adsorption of amphipathic molecules on the polymer particles; —- insoluble groups, ····· soluble groups; B) Equilibrium established in the course of a precipitation polymerization P = (growing) polymer particle; C) Schematic representation of flocculation due to multifunctional amphipathic molecules

Figure 39 A is a schematic representation of the adsorption of di-block, multiple-block, and graft copolymers on the surface of growing polymer particles. Soluble and insoluble portions of the dispersant molecules must be kept carefully in balance. If the insoluble part is too small, or if it interacts too weakly with polymer particles, then adequate adsorption will occur only when the dispersant concentration in the continuous phase is very high. If the soluble portion is too large, the dispersant will be present largely as aggregates or micelles with little tendency to dissociate and be adsorbed on the interface. Figure 39 B depicts the equilibrium situation. Finally, it is important to note that multifunctional amphipathic molecules like those shown in Figure 39 C can also function as weak flocculating agents.

In a well-stabilized dispersion, each particle is covered by a layer of freely moving polymer chains, which are in turn dissolved in the continuous phase. These layers prevent the frequently colliding particles from approaching so closely that Van der Waal's attractive forces become dominant. A simplified model (Fig. 40) suggests that the mechanism of steric stabilization involves an increase in the local concentration of polymer chains or segments as a result of overlapping and mutual chain interpenetration [496] as two polymer particles approach. This induces an osmotic pressure and increase in the free energy ΔG_R. To compensate for this effect, solvent flows into the regions of higher polymer concentration and drives the particles apart. A positive value of $\Delta G_R = \Delta H_R - T\,\Delta S_R$ can be due either to enthalpic effects (ΔH_R) or to entropic effects ($T\,\Delta S_R$). It is therefore possible to divide the contributions to steric stabilization into three categories [498]:

1) Enthalpic stabilization
   ΔH_R and ΔS_R are both positive
   $\Delta H_R > T\,\Delta S_R$
   The dispersion flocculates on warming
2) Entropic stabilization
   ΔH_R and ΔS_R are both negative
   $T\,\Delta S_R > \Delta H_R$
   The dispersion flocculates on cooling
3) Combined enthalpic – entropic stabilization
   ΔH_R is positive
   ΔS_R is negative

The dispersion is stable over a wide range of temperature.

Figure 40. Model for steric repulsion caused by the overlap of two spheres containing dissolved molecular chains [496], [497]
C = Concentration of the polymer chains in the adsorption layers

More complete discussions of steric stabilization may be found elsewhere [495], [498–503]. A survey of precipitation polymerization is available [504].

3.3.3.3. Suspension Polymerization

Definition. The term "suspension polymerization" includes a series of processes, all of which involve emulsifying monomers to droplets by stirring them in a suspending medium in which they are insoluble in the presence of a free-radical initiator, usually one that is soluble in the monomer. When the polymer formed is soluble in the monomer, nonporous spherical "beads" are formed, hence the term "suspension bead polymerization". If, however, the polymer precipitates during polymerization, the resulting polymer particles are composed of many smaller primary particles. They are opaque, usually possess an irregular surface, and may have substantial internal porosity. This type of polymerization has been called "suspension powder polymerization". The dispersants (protective colloids) are either macromolecules that are insoluble in the suspending medium or insoluble, usually inorganic, powders, the so-called Pickering emulsifiers [505]. Their function is first to assist in the formation of the initial monomer emulsion and then to stabilize the resulting polymer particle suspension. The following recipes are examples for suspension polymerization involving protective colloid and inorganic powder dispersants.

With protective colloid:	
Temperature	80 °C
Reaction time	8 h
Styrene	100 parts (by mass)
Water	200 parts (by mass)
Benzoyl peroxide	0.4 parts (by mass)
Poly(vinyl alcohol) [partially hydrolyzed poly(vinyl acetate)]	0.5 parts (by mass)

With pickering emulsifier:	
Temperature	80 °C
Reaction time	10 h
Styrene	100 parts (by mass)
Water	200 parts (by mass)
Benzoyl peroxide	0.2 parts (by mass)
Barium sulfate	1.0 part (by mass)
$C_{18}SO_3Na$	0.002 parts (by mass)

The term "suspension polymerization" is perhaps inappropriate, because precipitation and emulsion polymerizations also produce suspensions of polymer particles in a continuous phase. The distinction from precipitation polymerization is that it is initiated in a homogeneous mixture, while suspension polymerization takes place in an emulsion. The beads or powder particles produced in a suspension polymerization are roughly of the same size as the original monomer droplets with diameters on the order of 10^{-3} to 0.5 cm. Emulsion polymerization also starts with a monomer emulsion, but the initiator is usually one that is soluble in the continuous suspending phase rather than in the monomer. Moreover, the resulting latex particles are very much smaller (diameter range 5×10^{-6} to 3×10^{-5} cm or 0.05 to 0.3 μm) than the original monomer droplets. Borderline cases which might be called emulsion or suspension polymerization are discussed later in Section 3.3.3.4.

In the vast majority of cases, the suspending medium for suspension polymerization is water, although inverse-suspension polymerizations are also known and used commercially to produce very high molecular weight polymers and copolymers based on the comonomer acrylamide. Here a water-soluble monomer is dispersed in a hydrophobic organic suspending medium, usually in the presence of water in the disperse phase.

3.3.3.3.1. Qualitative Description

Generally, dispersants are employed at a concentration (relative to the aqueous phase) of 0.1 – 5 wt % in the case of protective colloids and 0.1 – 2 wt % for Pickering emulsifiers. A typical initiator concentration is 0.1 – 1 wt % relative to the monomer. The volume ratio monomer/aqueous phase is usually between 25 : 75 and 50 : 50, and the stereometric limit, which cannot be exceeded with spheres of uniform size, is 74 : 26.

The reactor vessel is usually a stirred tank. The monomer is subjected either to turbulent pressure fluctuations or viscous shear forces, which break it into small droplets that assume a spherical shape under the influence of interfacial tension. These droplets undergo constant collision (collision rate $\geq 1\ s^{-1}$), with some of the collisions resulting in coalescence. In the absence of stabilizers, a dynamic equilibrium is eventually established, leading to a stationary mean particle size. Individual drops do not retain their unique identity, but instead undergo continuous breakup and coalescence. This phenomenon can easily be demonstrated by the addition of a small amount of a monomer that has been labeled with a water-insoluble dye. The dye is rapidly distributed uniformly in the disperse monomer phase.

In some cases, an appropriate dispersant can be used to induce the formation of a protective film on the droplet surface. As a result, pairs or clusters of drops that tend to coalesce are broken up by action of the stirrer before the critical coalescence period elapses. A stable state is ultimately reached in which individual drops maintain their identities over prolonged periods of time. In this case, addition of dye-bearing monomer does not result in migration of the dye into other droplets. Such a system is described as a turbulence-stabilized emulsion.

In the simple case of a polymer that is miscible in all proportions with its monomer (e.g., styrene and methyl methacrylate), various viscosity states of the disperse phase are traversed during the course of polymerization. The initially nonviscous, liquid monomer is transformed gradually into an increasingly viscous solution of polymer in monomer, and as conversion proceeds the disperse phase acquires the characteristics of a solid polymer. Particularly in the tacky intermediate stage, individual polymer particles tend to form incompletely fused clumps. Coagulation at this critical stage of conversion is somewhat inhibited by the action of the dispersant, but other effective measures to reduce coagulation may also be taken, including adjusting the densities of the two phases to make them more similar, or by increasing the viscosity of the aqueous continuous phase. Rapid polymerization during the sticky stage minimizes the number of collisions among polymer particles and thus should reduce coagulation.

An experiment with dye-labeled monomer is also applicable when polymerization occurs in the disperse phase [506–508]. In this case dye-containing polymer beads generated in a parallel polymerization are added to the suspension during polymerization. It is observed that beyond a certain conversion (which depends on the reaction conditions) coagulation and particle breakup cease entirely. This is known as the "particle identity point" or the limit of dynamic equilibrium. Increasing the dispersant concentration (i.e., reducing the size of particles) displaces the identity point towards lower conversion [509], [510].

The schematic diagram in Figure 41 shows these fundamental relationships. The upper part of the diagram corresponds to dynamic equilibrium in a monomer emulsion that contains no dispersant, or to an emulsion undergoing polymerization that has not yet reached the identity point. The monomer phase is broken up into long strands by the stirrer, and these in turn fragment into spherical droplets due to interfacial tension forces. The droplets may then agglomerate into larger aggregates, finally coalescing into larger drops, which either break apart again due to stirring or collect as an extended monomer phase. The lower portion of Figure 41 shows the various stages that lie between the identity point and the end of the polymerization process. In a turbulence-stabilized emulsion, one in which monomer drops maintain their identity, the probability is high that individual drops will polymerize directly to primary beads. Nevertheless, even in a suspension bead polymerization, irregular particles sometimes appear, composed of many individual smaller polymer particles, a consequence of some clusters surviving past the identity point.

Figure 41. Schematic diagram of dispersion and polymerization in a suspension bead polymerization
A) Monomer emulsion in the absence of dispersant, or a polymerization mixture that has not yet reached the identity point; B) Polymerizing mixture after passing the identity point

A polymerizing bead with a diameter $d = 10^{-2}$ cm contains ca. 10^8 growing polymeric radicals. The effects of subdivision due to particle breakup in suspension polymerization are not anticipated to occur at the levels found in emulsion polymerization (polymer particles are submicron in size) where radical contents of 0.5 or lower per particle occur [511], [512]. Each bead may be regarded as a small, isolated reactor. For this reason, the observed polymerization kinetics correspond directly to those for bulk polymerization [506], [513], [514]. Here again the Trommsdorff – Norrish and glass effects must be taken into account, as must the effects associated with demixing when the polymer is insoluble in its monomer [459], [460], [462], [515]. Indeed, the process is sometimes referred to as a water-cooled bulk polymerization. To ensure that conversion is as complete as possible, it is common to employ mixtures of initiator types with different half-lifes, and to allow the polymerization temperature to increase in the final stages of conversion [516], [517]. With many industrially important suspension polymerizations, simply preparing a polymeric material is not sufficient. Often a particular particle-size distribution and morphology must be achieved, as in the manufacture of expandable polystyrene, or poly(vinyl chloride), whose particles must later absorb substantial quantities of plasticizer for some applications.

For what has already been said about the course of suspension polymerization, together with various results from the literature [507], [510], [513], [518], [519], it is possible to establish a number of special factors – apart from those common to all free-radical polymerizations – that exert an important influence on particle size and size distribution:

1) Geometric factors of the reactor: profile, type of stirrer, stirrer diameter D relative to the reactor dimensions, bottom clearance of the stirrer, and internal fittings
2) Operating parameters: stirrer velocity N, stirring and polymerization time, phase volume ratio φ, fill level of reactor, and temperature T
3) Substance parameters: dynamic viscosities η_c and η_d and densities ϱ_c and ϱ_d of the continuous and disperse phases, and interfacial the tension σ.

During monomer fragmentation, in collisions leading to agglomeration, and in deagglomeration of clusters, the most important consideration is the energy introduced into the reaction mixture per unit time. This can be expressed in terms of the mean rate of energy dissipation per unit mass $\bar{\varepsilon}$. In the case of a stirred reactor containing baffles and operated with a high Reynolds number, the following equation is applicable [520]:

$$\bar{\varepsilon} = KN^3D^2 \left[\mathrm{cm^2\,s^{-3}\ or\ W\,kg^{-1}}\right] \tag{3.19}$$

where K is a dimensionless constant that depends on the type of stirrer. Increasing the stirrer speed N causes a decrease in particle size.

The concentration of dispersant [S] determines the maximum particle surface area that can be stabilized and influences the interfacial tension. Increasing [S] leads to a decrease in particle diameter, as does lowering the interfacial tension. Increased disperse phase viscosity reduces particle breakup and thus leads to larger particles.

Figure 42. Schematic representation of the adsorption of partially hydrolyzed poly(vinyl alcohol) on the surface of a dispersed particle [510]
All − OH groups (omitted for clarity) are directed toward the aqueous phase, and residual acetate groups toward the disperse phase

3.3.3.3.2. Dispersants

Protective Colloid Dispersants. Organic protective colloids include natural products such as alginates, tragacanth, agar, and starch as well as modified natural polymers such as carboxymethylcellulose (sodium salt), hydroxyethylcellulose, and methylcellulose. Among the effective synthetic polymers are styrene – maleic anhydride copolymer, poly(methacrylic acid), poly(vinyl pyrrolidone), poly(vinyl alcohol), and partially hydrolyzed poly(vinyl acetate). The important feature of all these materials is their amphipathic character, which explains their ability to lower the interfacial tension and to concentrate at the monomer – water interface.

As shown in Figure 42, protective colloids are probably adsorbed in such a way that they form loops near the particle surface. In the case of partially hydrolyzed poly(vinyl alcohol), the residual acetate groups act as hydrophobic points of attachment, while the OH groups are directed into the continuous aqueous phase. The most important factor in dispersant effectiveness is an appropriate balance between hydrophilic and hydrophobic groups [521]; molecular mass is of considerably less significance. The wettability of a polymer can be varied by the addition of trace amounts of a low molecular mass surfactant.

Higher concentrations of protective colloid may cause a bead polymer to be contaminated by a small amount of a much more finely divided emulsion polymer. This should be avoided because it results in polymer loss during workup. The chance of encountering such a problem is enhanced by increased solubility of the monomer and initiator in the continuous phase. However, emulsion polymerization via homogeneous nucleation in the continuous phase can be suppressed by addition of a water-soluble inhibitor such as NH_4SCN or a copper salt [513], [522].

Powdered Dispersants (Pickering Emulsifiers). Finely divided, usually inorganic, insoluble solids may also be employed as dispersants in suspension polymerization [505], [513], [523]. Common choices include barium sulfate, talc, aluminum hydroxide, hydroxyapatite, tricalcium phosphate, calcium oxalate, magnesium carbonate, and calcium carbonate. It is advantageous to dissolve out the dispersant after the polymerization (e.g., in dilute acid), thereby minimizing polymer contamination. Monomer emulsions based on systems of this type are referred to as three-phase emulsions, a term introduced by Wenning [507]. In the case of a polymer that is insoluble in its monomer, a fourth phase occurs during the course of polymerization.

Solid dispersants must be wet by two immiscible liquids, and they must also exhibit a certain degree of self-adhesion. The wettability can be modified by adsorption of low molecular mass surfactants. This technique is referred to as modulation and it has much in common with techniques used in mineral flotation processes.

The wettability of a solid (S) by a liquid such as water (W) in the presence of a gas (G) depends upon the wetting angle α, which results

from equilibrium between three interfacial tensions:

$$\sigma_{SW} + \sigma_{WG} \cdot \cos\alpha = \sigma_{SG} \tag{3.20}$$

Figure 43. Wetting of a Pickering dispersant by monomer and water, modulated by addition of a surfactant
S solid; G gas; M monomer; W water
For further explanation, see text

Figure 43 A illustrates the significance of this relationship. An angle $\alpha = 0°$ corresponds to total wetting. For $\alpha = 90°$, $\sigma_{SW} = \sigma_{SG}$, and at $\alpha = 180°$ no wetting occurs. In a three-phase emulsion, two immiscible liquids compete for wetting the solid S: monomer M and water W. As indicated in Figure 43 B, there is again an equilibrium condition:

$$\sigma_{SW} + \sigma_{WM} \cdot \cos\alpha = \sigma_{SM} \tag{3.21}$$

Taking the example of barium sulfate as the dispersant in a styrene – water bead polymerization, the barium sulfate is at first wetted more effectively by water than by styrene, so $\sigma_{SW} < \sigma_{SM}$. Water wets the barium sulfate with a small contact angle α and $\cos\alpha$ is positive (Fig. 43 D). Addition of a surfactant whose polar groups are adsorbed on the barium sulfate makes the surface more hydrophobic (or lypophilic). As a result, σ_{SW} increases and σ_{SM} decreases, leading to the states shown in Figure 43 E and F. In the limiting case (Fig. 43 G), the particle is fully immersed in the monomer phase and loses its effectiveness as a dispersant. In the course of passing from D to F it is not uncommon for a phase reversal to occur: the oil-in-water emulsion is transformed into a water-in-oil emulsion and the polymer forms a block that contains water-filled voids [507]. It is clear that the limiting cases C and G are inappropriate for suspension polymerization. A good Pickering dispersant must possess amphiphatic characteristics, thus leading to one of the cases D – F. Many pure inorganic substances are completely wetted by water, the chief reason why modulation is so important in practice as a means of inducing the transition from C to D.

3.3.3.3.3. Mechanism of Particle Formation

Suspension polymerization always begins with dispersion of a monomer in water. It thus seems reasonable to first consider the formation of a monomer emulsion – or more generally, the formation of an emulsion of an organic liquid in water – and then examine the effects of polymerization in the disperse phase.

Droplet Size in an Emulsion Subject to Turbulent Mixing. Especially simple relationships should govern the suspension polymerization of a turbulence-stabilized emulsion in which single drops maintain their separate identities. However, such an emulsion must fulfill a series of conditions [524–526]:

1) Stirring must be sufficiently intensive to separate any droplet pairs or clusters that begin to form. The adhesive forces between two drops increase roughly linearly with the drop diameter d, while the forces exerted on the drops by stirring show a higher order dependence on drop diameter. The probability of separation therefore increases with diameter; given a particular stirring intensity, the diameter must remain above a specific minimum d_{min}:

$$d_{min} = C_1' \varrho_c^{-3/8} A(h)^{-3/8} \bar{\varepsilon}^{-1/4} \tag{3.22}$$

where C_1' is an empirical constant, ϱ_c is the density of the continuous phase and $A(h)$ is the energy required to separate to a distance $h = \infty$ two drops of diameter $d = 1$ initially separated by a distance h_0. The value of $A(h)$ is strongly dependent upon the thickness and characteristics of the adsorbed protective film. Equation (3.19) may be used

to convert Equation (3.22) to the following form:

$$d_{\min} = C_1' \varrho_c^{-3/8} A(h)^{-3/8} N^{-3/4} D^{-1/2} \quad (3.23)$$

If $d < d_{\min}$, drops will coalesce until a diameter $d_{\min}$ has been reached. If energy dissipation in the stirred reactor is not uniform (e.g., if only near the stirrer blades is it sufficient to break up drop clusters), then material circulation within the vessel must be sufficiently rapid to ensure that each cluster approaches the stirrer blades at least once during the critical coalescence time.

2) The dissipated stirring energy must not be so large as to cause significant breakup of individual drops, that is, the critical Weber number We (crit) or a maximum drop diameter $d_{\max}$ must not be exceeded:

$$We\,(\text{crit}) = C_2' d_{\max}^{5/3} \varrho_c \sigma^{-1} \bar{\varepsilon}^{2/3} \quad (3.24)$$

which is transformed by using Equation (3.19) into:

$$d_{\max} = C_2 \varrho_c^{-3/5} \sigma^{3/5} N^{-6/5} D^{-4/5} \quad (3.25)$$

where C_2' and C_2 are empirical constants and σ is the interfacial tension. Equation (3.25) is only applicable if the viscosity ratio η_d/η_c is not too large. Otherwise, the stable drop diameter increases with increasing values of η_d/η_c, because turbulent oscillations in the disperse phase are damped (viscosity stabilization of drop size).

3) A density difference between the phases results in a tendency towards settling, and this increases with increasing drop size. Stirring energy must be sufficient to counteract this tendency. The maximum drop diameter $d_{\max}$ that can be sustained in an emulsion at a particular rate of energy dissipation $\bar{\varepsilon}$ is given by:

$$d_{\max} = C_3' \left(\frac{\varrho_c}{\varrho_d - \varrho_c} \right)^3 \frac{1}{g^3} f(\varphi) \bar{\varepsilon}^2 \quad (3.26)$$

and using Equation (3.19) one obtains

$$d_{\max} = C_3 \left(\frac{\varrho_c}{\varrho_d - \varrho_c} \right)^3 \frac{1}{g^3} f(\varphi) N^6 D^4 \quad (3.27)$$

where C_3' and C_3 are empirical constants, g is the acceleration due to gravity, φ is the volume ratio (disperse phase volume/continuous phase volume), and $f(\varphi)$ is an empirical function.

According to [524–526], turbulence stabilization is only possible if the drop diameter is larger than $d_{\min}$ as given by Equation (3.23), and smaller than both $d_{\max}$ from Equation (3.25) and $d_{\max}$ from Equation (3.27). It is reasonable to assume that the Sauter mean diameter given by

$$d_{32} = \frac{\Sigma \eta_i d_i^3}{\Sigma \eta_i d_i^2} \quad (3.28)$$

is proportional to the maximum diameter $d_{\max}$. Figure 44 illustrates these relationships. Stability is achieved only in the shaded region between the lines defined by Equations (3.23), (3.25), and (3.27). If $\bar{\varepsilon} < \bar{\varepsilon}_{\min}$, then $d_{\min}$ (coalescence) $> d_{\max}$ (demixing) and the emulsion will separate into two phases. On the other hand, if $\bar{\varepsilon} > \bar{\varepsilon}_{\max}$, then $d_{\min}$ (coalescence) $> d_{\max}$ (breakup) and the emulsion will be unstable because the energy necessary for separating a droplet pair is sufficient to breakup the droplets themselves.

Figure 44. Theoretical relationship governing the fragmentation (Eqs. 3.22 and 3.23), coalescence (Eqs. 3.24 and 3.25), and demixing (Eqs. 3.26 and 3.27) of droplets in a stirred reactor. Only in the shaded region can a turbulence-stabilized emulsion form [525]

A prerequisite for the validity of Equations (3.22) – (3.27) is the applicability of Kolmogoroff's theory of local isotropy [527–529]. The characteristic length L of the energy-containing large eddies ($L \approx 0.08\,D$, according to

[244]) must be larger, and the characteristic length l of the energy-dissipating small eddies [$l = (\gamma_c^3/\varepsilon)^{1/4}$], where γ_c is the kinematic viscosity of the continuous phase] must be much smaller than the drop diameter d (i.e., $L \gg d \gg l$). Equations (3.24) and (3.25) [531–534] as well as (3.22) and (3.23) [525], [526], [535] have been verified experimentally. Nevertheless, they apply only for very small phase ratios $\varphi < 0.015$, which are unrealistic for industrial suspension polymerizations. The polymerizing system is also subject to nonnegligible effects of the viscosity ratio η_d/η_c. In [536], for example, this has been taken into account by introduction of the viscosity group $\eta_d(\varrho_d\,\sigma\,d)^{-1/2}$, which depends only on the physical properties of the disperse phase. At higher phase ratios, both d_{32} and d_{max} increase with increasing distance from the stirrer [534], [537], [538]. Various corrections [531], [534], [539], [540] have been suggested for Equation (3.25), all of which take the form:

$$\frac{d_{32}}{D} = A\,(1+B\varphi)\,We^{-3/5} \tag{3.29}$$

where A and B are numerical constants. For phase relationships such as those applicable on an industrial scale it is therefore not possible to assume a homogeneous energy-dissipation rate ε; instead, it must be anticipated that ε is large in the vicinity of the stirrer, becoming smaller in more remote circulation zones. A simulation program has been described [541–543] that approaches this problem by dividing the reactor into various stirring and circulation zones and then applying Monte Carlo methods.

The Size of the Polymer Particles. Conversion of a monomer into polymer increases the viscosity η_d and density ϱ_d of the disperse phase, and lowers the volume phase ratio φ. The interfacial tension σ also changes, and grafting reactions between polymeric radicals on the organic protective colloid and the monomer may have to be accounted for. As has been demonstrated by Hopff et al. [544–547] in the case of a suspension bead polymerization of methyl methacrylate with a relatively high concentration of a protective colloid [poly(vinyl alcohol), Mowiol N 70 (88)], systems exist in which the final particle size is already established at very low conversion. Polymerizing droplets maintain their identity, and subsequent reduction in stirring speed has no influence on particle size. Apparently, a turbulence-stabilized state is reached at the very onset of polymerization. Evaluation with respect to particle size is particularly straightforward in this case, since changes in the above-mentioned parameters during polymerization are irrelevant.

A series of experiments in geometrically similar reactors (see Fig. 45) coupled with dimensional analysis, permitted derivation of the following dimensionless equation in the case of this especially simple system:

$$\frac{d_{50}}{D} = kRe^{0.5}We^{-0.9}Fr^{-0.1}\left(\frac{\eta_d}{\eta_c}\right)^{0.1}\varphi^0 \tag{3.30}$$

where d_{50} is the bead diameter below which 50 wt % of the particles pass through the sieve (in other words 50 wt % of the particles have a diameter less than d_{50}), D is the stirrer diameter, which throughout the experiments was kept in a constant ratio to the reactor diameter, and k is a numerical constant.

Figure 45. Dependence of the bead diameter d_{50} on the stirrer velocity N [545]
Experiments conducted in four geometrically similar stirred reactors with stirrer diameter D
Curve parameter: protective colloid concentration in g/100 cm^3

The dimensionless groups are:

$$Re = \left(\frac{D^2 N \varrho_c}{\eta_c}\right) = \text{ratio of inertial/viscous forces}$$

$$Fr = \left(\frac{DN^2}{g}\right) = \text{ratio of inertial/gravitational forces} \quad (3.30a)$$

$$We = \left(\frac{D^3 N^2 \varrho_c}{\sigma}\right) = \text{ratio of inertial/interfacial forces}$$

It follows that $d_{50} = kN^{-1.5}$

A relationship similar to Equation (3.30) has been found for the suspension polymerization of vinyl chloride [548], [549]. In this case, however, a large particle diameter region was identified with $d = kN^{-1.9}$ at low stirrer speeds (with correspondingly large particle diameters) as well as a fine-particle size region with $d = kN^{-0.6}$. An analogous effect has also been reported for styrene [550].

In contrast to the very early establishment of particle diameter in the experiments of HOPFF et al., dye-labeling experiments have shown that in other systems [506–508], [550], [551] the particles reach the so-called identity point only at high conversion. With these systems it is apparently necessary to take into account the time and conversion dependence of the parameters enumerated above. Another important observation [550], [552] is the fact that in certain systems the stirring time in which the unpolymerized emulsion reaches its final droplet diameter is longer than that taken by the polymerizing system to reach 50 % conversion. A faster polymerization would therefore give larger polymer particles due to viscosity stabilization.

The problems associated with scaling up from small to industrial scale, particularly for particle size, are an important concern in suspension polymerization. In principle, Equation (3.30) should be applicable, suggesting that all that is required for maintaining constant d/D when scaling up is to keep Re, We, Fr, and η_d/η_c constant. However, Equations (3.30 a) show that this is not possible without changing the composition of the system. Furthermore, it is d, not d/D, that must be kept constant in an industrial scaleup. To what extent it is possible at high Reynolds numbers to avoid an exact similarity transformation and scale the process up on the basis, for example, of [553], [554]

$$\frac{d}{D} = kW e^{-0.6} Eu^{-1.0} \quad (3.31)$$

or

$$d \sim D^{-0.8} N^{-1.2} \quad (3.32)$$

has not yet been established experimentally (Eu is here a modified power number in power per unit volume). A not further defined suspension polymerization of methyl methacrylate in 1 % polyacrylamide solution was transformed with constant particle size on the basis of

$$N_1 = N_2 \left(\frac{D_2}{D_1}\right)^{2/3} \quad (3.33)$$

from a laboratory reactor (1) with $D = 10.1$ cm to a half-tonne scale (2) with $D = 81.2$ cm [555].

3.3.3.3.4. Industrial Applications

Suspension polymerization is used for producing a wide variety of polymer types, the most important of which are mentioned briefly. Standard polystyrene for use in injection molding is manufactured by suspension bead polymerization, as is poly(methyl methacrylate) and its copolymers containing small amounts of acrylate esters. Clear transparent polymers are often required, so formulations involving Pickering dispersant (e.g., $MgCO_3$) that can be dissolved out of the polymer with dilute acid after polymerization are particularly advantageous.

In the case of styrene – acrylonitrile copolymers, the method of choice for batch suspension polymerization is normally that involving the azeotropic composition to minimize compositional drift. Nevertheless, complications often arise, because considerably more acrylonitrile than styrene dissolves in the aqueous continuous phase. As conversion proceeds, acrylonitrile diffuses into the polymer particles and the monomer ratio in the beads changes, causing the composition of the copolymer to change as well [556]. The same phenomenon can accompany copolymerization in heterogeneous systems generally [557].

High-impact polystyrene and ABS are often prepared in a combined process. This begins with a solution of polybutadiene in styrene or

styrene/acrylonitrile and permits bulk polymerization to occur under stirring until phase reversal or inversion has occurred. Water and dispersant are then added and the polymerization is completed in suspension [558], [559].

Expandable polystyrene is prepared by suspension polymerization in the presence of a blowing agent, such as pentane [560], [561]. It is also possible to introduce the blowing agent in a second step after polymerization, allowing it to diffuse into the beads [562], [563]. Warming to 80 – 110 °C, generally with steam, causes the beads to expand by foaming, their volume increasing by a factor of ca. 30 – 50. Particle size and size distributions both play important roles. For example, if thin-walled objects are to be made from expandable polystyrene, especially small polymer particles are required. The unfoamed product is fractionated by sieving prior to drying. Figure 46 shows a schematic of a typical EPS production facility.

Figure 46. Schematic representation of the manufacture of Styropor by batch suspension polymerization
a) Mixing tank; b) Stirred reactor; c) Puffer tank; d) Centrifuge; e) Sieving; f) Drying; g) Silo; h) Packaging

The required amount of deionized water is loaded into the reactor at ambient temperature and agitation is started. Styrene and the initiator pair, AIBN or benzoyl peroxide plus a finishing initiator such as di-*tert*-butyl peroxide or *tert*-butyl peroxybenzoate are pumped into the reactor at a constant rate, while the stabilizer, either an inorganic, insoluble, finely divided powder or a polymeric steric stabilizer is added. The reactor is closed and the heating cycle starts. Droplet size development occurs during the heating cycle. When the polymerization temperature is reached, between 75 °C and 95 °C depending on the initiator type, the polymerization proceeds until a conversion in the range 32 – 35 % is obtained. This point marks the beginning of the so-called "sticky-stage" at which point the coalescence rate begins to increase, causing the beads to grow from a mean particle diameter of about 0.2 mm to the desired size, depending on the original stabilizer formulation, for the final application of the resin product. During this stage of the process, particle size is monitored by periodic sampling of particle size growth rate. Additional stabilizer may be added if the growth rate is too large. At 65 – 68 % conversion of monomer, the identity point is reached. At this point the particle viscosity is sufficiently large that collisions between particles are elastic and particle size growth ceases. In addition, the density of dispersed and continuous phases are almost identical, and the suspension is very stable. Autoacceleration of the polymerization rate becomes appreciable at the identity point and increases until ca. 95 % conversion where a glassy-state transition occurs and the beads become hard. Once the beads are hard the reaction mixture is heated to a temperature above the glass transition temperature of the polystyrene ($T_g \approx 100$ °C). During heating, the reactor is pressurized with a blowing agent (5 – 8 % with respect to polymer), a low-boiling hydrocarbon ($C_4 - C_7$). The reactor is then pressurized with nitrogen at 700 – 950 kPa and the so-called impregnation stage starts and proceeds for 3 – 8 h. During impregnation the blowing agent diffuses into the beads. At the same time, the free volume increases, and the finishing initiator rapidly generates radicals, causing a relatively rapid increase to a monomer conversion of ca. 99.9 %. The impregnation time should be sufficient to allow the blowing agent to reach the core of the particle and to cause the breakup of hydrocarbon domains within the polymer matrix, giving a uniform distribution. At the end of the impregnation stage the suspension is cooled to 20 – 30 °C, depending on the blowing agent type, to freeze in the ingredients and prevent bead expansion during handling. Some typical properties of an EPS grade are:

Monomer conversion	> 99.9 %
$\bar{M}_W \times 10^{-3}$	200 – 300
Polydispersity	2.2 – 2.4
Mean particle diameter $\bar{d}$	0.4 – 1.5 mm
PSD breadth $\sigma/\bar{d}$	0.20 – 0.25
Blowing agent concentration	5.0 – 8.0 %

Table 3 lists required properties of the bead for different applications.

Table 3. EPS bead properties and applications

$\bar{d}$, mm	$\sigma/\bar{d}$	Density, kg/m^3	Use
1.5	0.20	8 – 16	construction (insulation)
1.0	0.15	12 – 20	packaging
0.4	0.10	50 – 70	coffee cups

Figure 47. Growth path for EPS beads (mean diameter $\bar{d}$ versus monomer conversion) during suspension polymerization of styrene [564]
Stage I: breakup and coalescence rates are about equal
Stage II: coalescence rate exeeds breakup rate
Stage III: conversions exceed identity point (no further breakup and coalescence)

Suspension polymerization processes give a rather broad PSD. In some EPS applications, such as for coffee cups, a very narrow PSD is required and for this grade the suspension polymerization process is commonly carried out in two stages to minimize off-spec resin. In the first stage, styrene is polymerized to give the narrowest PSD possible and then the suspension is removed from the reactor and the polymer particles are classified by sieving to give the required narrow PSD. The particles are then resuspended in the reactor to permit impregnation with a blowing agent in the second stage. Suspension polymerization for EPS production is a three stage process. In the first stage, the particle viscosities are low and an equilibrium particle size is obtained (rates of droplet breakup and coalescence are equal). In the second stage, where the viscosity of the particles is sufficiently high, the particles grow (coalescence rate exceeds breakup rate). For EPS, VILLALOBOS [564] observed that no further breakup occurs beyond 50 % monomer conversion when the particle viscosity is about 10^4 cP. Addition of stabilizer is used to obtain the desired $\bar{d}$ at the identity point. At the identity point both breakup and coalescence rates are zero. At the end of stage II, the PSD has been established except for some minor shrinkage in the third stage due to density differences between monomer and polymer. Figure 47 shows a typical growth path for EPS beads with $\bar{d} = 0.425$ mm. Since $\bar{d}$ continually increases during stage II, the variance of the PSD also increases significantly. Figure 48 shows the broadening of the PSD with conversion observed by KONNO et al. [565].

△ 45 % monomer conversion, 240 min

A potentially practical method of narrowing the PSD is to speed up the polymerization rate, by, for example, employing bifunctional initiators [566] to reduce the time for coalescence in stage II. This approach is based on the interaction of polymerization variables with the fluid dynamical variables to achieve a desired PSD.

Suspension polymerization is the most important commercial process for the manufacture of poly(vinyl chloride) [→ Poly(Vinyl Chloride), Chap. 4.1.]. Porous beads with a rough surface are advantageous for rapid incorporation of plasticizers. This effect can be achieved by suitable choice of dispersant [515], [567–569] or by the addition of a few percent *n*-butane [570], [571]. A review provides a comprehensive survey of polymer particle morphology development during suspension polymerization of vinyl chloride [572]. A serious attempt to predict the size distribution of primary polymer particles

and bead porosity has been made [573]. Ion-exchange resins are almost always made by suspension polymerization giving spherical beads in the size range ca. 0.3 – 1.2 mm. Most products use polystyrene cross-linked with divinylbenzene to which functional groups are subsequently attached (e.g., $-SO_3$ groups by treatment with sulfuric acid, chlorosulfonic acid, or SO_3). Weakly acidic cation exchangers are prepared by copolymerization of divinylbenzene with methacrylic acid, acrylate esters of lower alcohols, or acrylonitrile. In this case the functional groups are incorporated during polymerization, or they result from subsequent hydrolysis. Macroporosity is achieved by addition of an inert liquid which is a solvent for the monomer but a nonsolvent for the polymer and which can readily be removed after polymerization is complete [574].

With water-soluble monomers, especially acrylamide and comonomers (e.g., acrylic acid, dimethylaminoethyl acrylate) it is common to use "inverse microsuspension polymerization" in which a concentrated aqueous solution of the monomer is emulsified in an oily continuous phase, usually a hydrocarbon, and then polymerized with either an oil- or water-soluble initiator. When an oil-soluble initiator is used with an aromatic continuous phase, the kinetics have been shown to resemble those of emulsion polymerization [575–577]. The resulting polymer particles are much smaller than the original monomer droplets, and the number of radicals per polymer particle is small (< 1). However, when paraffinic oil continuous phases are used, as is most common commercially, the locus of polymerization is in the monomer droplets. This has been verified by dynamic light scattering measurements which failed to detect inverse micelles and indicated a constant particle morphology with increasing conversion [578–580]. The polymerization therefore physically and kinetically resembles a suspension polymerization and the prefix "micro" is added because average polymer particle diameter is nominally 1 μm, well below the usual size range for suspension polymerization. Suitable dispersants include Pickering emulsifiers, polymers bearing hydrophilic groups, or block or graft copolymers whose components differ in solubility [581–583].

Stirred batch reactors are by far the most common for suspension polymerization, reaching sizes up to 200 m^3. Their construction presents numerous engineering problems [554], [584–588]. The most effective stirring in large reactors is achieved with impellers driven from below. The patent literature describes a wide variety of approaches for continuous suspension polymerization. Apparently to date there are no continuous suspension polymerizations carried out commercially. The main problems relate to the fact that, on the one hand, it is important to assure the most uniform shear gradients possible (i.e., total back-mixing) to establish the desired particle size distribution and to prevent coagulation and clumping in dead spaces. On the other hand, maximum conversion is also desirable, and this is only possible in a continuous process with a narrow residence time distribution. Diffusion of monomer through the continuous phase may not be sufficiently rapid to ensure that conversion is the same in all particles, independent of their residence time in the reactor. A particle that has a long residence may have a very low monomer concentration with concomitant high level of branching, cross-linking, and gel.

3.3.3.4. Emulsion Polymerization

Emulsion polymerization is probably the most versatile of the polymerization techniques, applicable with many monomer types in batch, semi-batch (semicontinuous), and continuous processes. The product is a finely divided (particle diameters ca. 0.05 – 0.3 μm) aqueous polymer dispersion (latex) containing up to 60 wt % solids, which can either be used in latex form or first coagulated and dried. Particle size distribution may play an important role in the final application, as with emulsion PVC paste products. However, with some polymers (e.g., styrene – butadiene rubber), the latex particles are coagulated during work up to rubber bales and so their size is irrelevant, except perhaps in the coagulation stage of the process.

Suspension and emulsion polymerization are both begun in an aqueous emulsion of a monomer with low water solubility. In emulsion polymerization, however, the locus of polymerization is in latex particles and not monomer droplets, the latex particles being much smaller and having a much larger total interfacial area [589]. Various theories exist for the mechanism

of latex particle formation, differing primarily with respect to the effect of the degree of monomer solubility in water. The polymerization process in the latex particles is also quite different from that in monomer – polymer droplets in suspension polymerization, because the primary radicals generally form in the aqueous continuous phase and migrate from there into the latex particles. The most obvious difference in the kinetics compared to solution or suspension polymerization is the fact that polymerization rate and molecular mass of the polymer produced may be increased simultaneously in emulsion polymerization. Various explanations have been offered for the observed kinetic behavior. The differences relate primarily to the question of whether or not radicals, once they have entered a latex particle, are then capable of leaving again and entering other particles. The decisive factors are the prevalence of chain transfer to small molecules (e.g., monomer) and the water solubility of the monomer. Finally, the Trommsdorff – Norrish effect also plays an important role but with some modified features. It should also be noted that polymer particles in emulsion polymerization have a rather high polymer concentration even at their birthtime.

Several reviews discuss kinetics and mechanisms [590–602] as well as mathematical models [357], [603] applicable to emulsion polymerization. Proceedings from various symposia on emulsion polymerization and related topics have also been published [604–611].

3.3.3.4.1. Theories of Emulsion Polymerization

Qualitative Theory. The qualitative theory of batch emulsion polymerization is due primarily to the groups of Fikentscher [589], [612–614] and Harkins [615–618]. It is based on a system consisting of water, a monomer with low water solubility, an emulsifier, and a water-soluble initiator that decomposes to produce radicals in the aqueous phase (see Fig. 49). The emulsifier concentration is above the critical micelle concentration (CMC) and thus micelles form. The hydrophobic interior of the micelles contains solubilized monomer, which is apportioned by diffusion out of the emulsified monomer drops and through the aqueous phase. Initiator decomposes in the water phase to generate primary radicals, which propagate with monomer dissolved in water to form oligomeric radicals. When an oligomeric radical enters a micelle it propagates rapidly with solubilized monomer to form a polymer particle. In a typical emulsion polymerization there are about 10^{13} monomer droplets per liter of emulsion, with an average droplet size of about 3 µm. This compares with ca. 10^{18} micelles, each consisting of ca. 100 emulsifier molecules with a diameter of about 5 – 10 nm. The total interfacial area of the micelles is about three orders-of-magnitude larger than that of the monomer droplets. Consequently, oligomeric radicals in the aqueous phase are much more likely to diffuse into a micelle swollen with monomer than into a monomer droplet. Polymerization thus occurs almost exclusively in the micelles and polymer particles which are later formed, consuming monomer that arrives by diffusion through the aqueous phase from the monomer droplets. Micelles are thus gradually transformed into polymer (latex) particles with a diameter of ca. 0.1 µm and a concentration of ca. 10^{17} particles per liter. As polymerization proceeds a form of subdivision occurs, with monomer being transferred from large monomer droplets with a concomitant increase in total interfacial area. As a consequence, micelles are consumed by being "stung" with an oligomeric radical from the water phase and by being adsorbed on new interfacial area which is continuously being formed. When all the micelles are consumed and the concentration of emulsifier in the aqueous phase is just about to fall below the CMC, polymer particle nucleation (via micellar nucleation) ceases. The interval from the start of the generation of oligomeric radicals in the aqueous phase to the point where micelles have been consumed is called Stage I in the emulsion polymerization process. At the end of Stage I, as illustrated in Figure 50, there is a rapid drop in the free emulsifier concentration (which throughout Stage I is equal to the CMC due to equilibrium with micelles) and the surface tension (head-space gas/latex) rises rapidly from its previously stationary value. Because the fractional coverage of the surface of polymer particles falls after the end of Stage I problems with particle stability and coagulation may occur.

Figure 50. Overall rate of reaction R_p and surface tension σ as a function of conversion during the three phases of emulsion polymerization (schematic)

Stage II is known as the polymer particle growth stage, during which the number of particles remains constant (in the absence of coagulation), as does the monomer concentration $[M]_p$ in the latex particles as a result of monomer diffusion from the reservoir of monomer droplets. Because of the extremely high interfacial areas (polymer particle/water and monomer droplet/water) and associated very rapid mass transfer of monomer, there is an equilibrium with respect to monomer transfer from monomer droplets to polymer particles (the chemical potential of monomer is the same in all three phases, monomer droplet/water/polymer particle). The interfacial energy per unit volume for the small polymer particles contributes significantly to the free energy and thus must be accounted for as shown in Equation (3.34):

$$\frac{2V_1\sigma}{rRT} = -\left\{\ln(1-\varphi_p) + \varphi_p + \chi\varphi_p^2\right\} \tag{3.34}$$

where V_1 is the molar volume of monomer, σ is the interfacial tension (latex particle/aqueous phase), r is the radius of the latex particle; φ_p is the volume fraction of polymer in the latex particle ($\varphi_m = 1 - \varphi_p$, with φ_m the volume fraction of monomer); χ is the Flory – Huggins polymer – solvent interaction parameter [435, p. 522], [455].

Swelling and monomer concentration $[M]_p$ both increase with decreasing interfacial tension σ, increasing particle radius r, and with a decrease in the parameter χ (which is equivalent to the monomer being a better solvent for the polymer; only when $\chi < 0.5$ are monomer and polymer completely miscible).

Since σ and r increase simultaneously during Stage II, both φ_m and $[M]_p$ remain relatively constant [619], [620] provided monomer droplets are present. The constancy of N_p (the total number of polymer particles per liter) and $[M]_p$ usually results in a constant polymerization rate R_p during Stage II.

Stage III, known as the depletion or monomer finishing stage, begins with the disappearance of all monomer droplets. The only reservoir of monomer for the polymerization in the latex particles is the aqueous phase. This is hardly sufficient and in Stage III the monomer concentration $[M]_p$ falls with time and conversion. The viscosity of the latex particles increases dramatically due to increase in the number of physical chain

entanglement points as the polymer concentration increases. The self-diffusion coefficients of polymeric radicals fall and the Trommsdorff–Norrish effect, which was active in both Stages I and II, increases in intensity with monomer conversion [621], [622]. This can lead to a heat-kick when temperature control of the polymerization is inadequate. Another phenomenon which may occur is a glassy-state transition in the latex particles. This occurs when the polymerization temperature is lower than the glass transition temperature of the polymer being synthesized. The monomer acts as a plasticizer for the polymer, and propagation essentially ceases when the polymer – monomer solution undergoes glass transition at the polymerization temperature.

Overall Rate of Polymerization with a Given Number of Particles. To calculate the rate of polymerization it is necessary to know the number of polymer particles containing n radicals (or the average number of radicals per latex particle). Assuming a stationary state, the following particle population balance may be written [623]:

$$\underbrace{\frac{R_i}{N_p} \cdot N_{n-1}}_{\text{entry}} + \underbrace{\frac{K_0 S}{v}(n+1)N_{n+1}}_{\text{exit}} + \underbrace{\frac{K_{tp}}{v}(n+2)(n+1)N_{n+2}}_{\text{termination}} =$$

$$\underbrace{\frac{R_i}{N_p} \cdot N_n}_{\text{entry}} + \underbrace{\frac{K_0 S}{v} \cdot nN_n}_{\text{exit}} + \underbrace{\frac{K_{tp}}{v}(n)(n-1)N_n}_{\text{termination}} \quad (3.35)$$

The formation rate of particles with n radicals equals the disappearance rate of particles with n radicals.

where R_i is the rate of radical entry (radical $cm^{-3}\,s^{-1}$); K_0 is the rate constant for radical exit (cm/s); S is the particle surface area (cm^2); K_{tp} is the rate constant for bimolecular termination in the polymer particles (cm^3 $radical^{-1}\,s^{-1}$); and v is the particle volume.

Smith and Ewart have derived expressions for several limiting cases [623]:

Case 1) Rate of radical exit $\gg$ rate of radical entry

$$\frac{K_0 S}{v} \gg \frac{R_i}{N_p} \quad (3.36)$$

In this case the average number of radicals per particle which is given by

$$\bar{n} = \frac{\sum nN_n}{\sum N_n} \ll 1 \quad (3.37)$$

is much less than unity.

Case 2) Rate of termination > rate of entry $\gg$ rate of exit

$$\frac{K_{tp}}{v} > \frac{R_i}{N_p} \gg \frac{K_0 S}{v} \quad (3.38)$$

This case leads to $\bar{n} = 1/2$ on the basis of the following simple considerations [511]: when an oligomeric radical enters a polymer particle containing no radicals polymerization is rapid and a particle containing one radical is formed. When a second radical enters this particle, termination is instantaneous and two radicals are annihilated (two radicals cannot coexist for any significant time). Instantaneous termination occurs for small latex particles when the termination constant K_{tp} is sufficiently large. Since the exit rate is negligibly small, a given latex particle will alternately contain either one or no radical. Thus averaged over time $\bar{n} = 1/2$. One can also obtain this result with a simple kinetic analysis: application of the stationary-state hypothesis for radicals:

$$R_i = 2R_i\left(\frac{N_1}{N_p}\right) \text{ and } \bar{n} = \frac{N_1}{N_p} = 1/2 \quad (3.39)$$

where $N_p = N_0 + N_1$.

Since water-phase termination affects R_i by the same factor (on both sides of the equation) its magnitude is irrelevant. Radical scavengers in the water phase will for the same reasons have no effect on $\bar{n}$. Radical scavengers in the polymer particles would, however, lower N_1 and $\bar{n}$ to values below 1/2.

Case 3) Rate of exit $\ll$ rate of entry $\geq$ rate of termination

$$\frac{K_0 S}{v} \ll \frac{R_i}{N_p} \geq \frac{K_{tp}}{v} \quad (3.40)$$

Here the latex particles are effectively flooded with radicals, so that $\bar{n} \gg 1$, and it can be shown that the kinetics in the polymer particles correspond to those in bulk polymerization. During the buildup of radicals in the particles with time,

radical entry rate will exceed the bimolecular termination rate; however, a stationary-state with respect to radical concentration will be reached as with bulk polymerization.

A general solution to Equation (3.35) has been provided by STOCKMAYER [624] with minor corrections by O'TOOLE [625]. After multiplication by v/K_{tp} and the substitutions

$$\alpha = \frac{vR_i}{N_p K_{tp}}, \quad m = \frac{K_0 S}{K_{tp}}, \quad a = (8\alpha)^{1/2}$$

Equation (3.35) is transformed into:

$$N_{n+2}(n+2)(n+1) + N_{n+1}(n+1)m + N_{n-1}\alpha = N_n[n(n-1) + mn + \alpha]$$

Solutions to this equation follow:

$$\bar{n} = \frac{a}{4}\frac{I_0(a)}{I_1(a)} \quad \text{for } m = 0 \tag{3.41a}$$

$$\bar{n} = \frac{a}{4}\frac{I_m(a)}{I_{m-1}(a)} \quad \text{for } 0 < m < 1 \tag{3.41b}$$

$$\bar{n} = \frac{(m-1)}{2} + \frac{a}{4}\frac{I_{m-2}(a)}{I_{m-1}(a)} \quad \text{for } m \geq 1 \tag{3.41c}$$

Here the expressions $I_m(a) = i^{-m} J_m(ia)$ are first-order Bessel functions, tabulated in [626], [627]. An approximate solution to the Bessel functions is available in [597, pp. 556, 602 ff]. Figure 51 shows the dependence of $\bar{n}$ on a and m. Knowledge of $\bar{n}$ allows calculation of R_p using the relationship:

$$R_p = K_p [M]_p \bar{n} N_p / N_A \tag{3.42}$$

where N_A is Avogadro's number.

Figure 51. Average number of radials $\bar{n}$ in latex particles as a function of the parameters a and m Equation (3.41) [625]

GARDON has described a series of investigations in which the assumption $dN_n/dt = 0$ in Equation (3.35) was not made [620], [628]. Realistic parameters when used in the nonstationary form of Equation (3.35) led to the conclusion that negligible errors were introduced in Equation (3.35) by neglecting the transient accumulation term [597, pp. 566, 602 ff], [629]. One possible exception is a system subject to a very large Trommsdorff–Norrish effect and where $K_{tp} \gg K_p$ is no longer valid. In principle, Equations (3.41) and (3.42) may be used to estimate the magnitude of the Trommsdorff–Norrish effect in emulsion polymerization.

Using an appropriate relationship for the termination constant K_{tp} and its dependence on polymer concentration or monomer conversion in Stage III, one can calculate $\bar{n}$ versus conversion as shown in Figure 52 for styrene emulsion polymerization. Figure 53 shows calculated conversion – time curves for several monomer systems using appropriate expressions for K_{tp} as a function of conversion. It is clear that the Trommsdorff–Norrish effect is of greater importance in emulsion polymerization when Case 2 kinetics are obeyed and when the polymer particles are larger (vinyl acetate is clearly a Case 1 system).

○ experimental data

It seems remarkable that the empirical relationships for K_{tp} as a function of conversion found for bulk polymerization can be applied so effectively to emulsion polymerization, as shown in Figure 53. Part of the answer as to why this agreement exists may be that when two radicals cannot coexist in a polymer particle (instantaneous termination), $\bar{n}$ is independent of K_{tp}. At higher conversions when $\bar{n}$ is clearly > 0.5 for a Case 2 system, the size of polymeric radicals in the latex particles should depend on the rates of termination and radical entry when chain transfer to monomer is negligible. However, if chain transfer to monomer is significant, the size of polymeric radicals depends only on polymerization temperature and not on the type of polymerization process.

To explain kinetic results obtained with styrene, for which R_p fails to decline on entering Stage III, it has been suggested that one should consider uneven swelling of latex particles composed of a monomer-rich shell and a polymer-rich core [631–633]. The monomer concentration in the shell, which is the site of polymerization, should then remain constant even in Stage III. These kinetic arguments have been criticized by several other authors [630], [634], [635] and the observed facts can also be largely accounted for by considering the Trommsdorff – Norrish effect in which a simultaneous decrease in $[M]_p$ and K_{tp} effectively compensate for each other. However, experiments involving the polymerization of styrene on a seed latex where either the monomer or the seed latex is labeled [632] clearly suggest that in Stage II the monomer does indeed polymerize preferentially in the outer shell. The contradiction with respect to Equation (3.34), which has also been verified experimentally [620], [636], [637], has not been adequately explained. Neutron scattering experiments indicate that the polystyrene latex particles are uniformly swollen by styrene.

If the exit rate of radicals is negligible ($m = 0$), then a sudden reduction in the rate of initiation in the water phase to $R_i = 0$ should result in a constant R_p. In fact, however, experiments involving intermittent γ-Co [638] or UV radiation [639] as initiator reveal that R_p decreases rapidly as soon as irradiation ceases. This suggests that radicals can be desorbed from one latex particle and reabsorbed in another. There thus exists an alternative termination process: interparticle termination that reduces the mean concentration of radicals $\bar{n}$. Equation (3.35) makes no provision for possible reentry of a desorbed radical. According to UGELSTAD [640–643], the rate of radical entry R_i is a function of both the rate of radical formation in the aquous phease by initiator decomposition $R_{i,w}$ and the rate of desorption, diminished by the rate of termination in the aqueous phase:

$$R_i = R_{i,w} + K_d \sum_{n=1}^{\infty} nN_n - 2K_{tw}\,[R^{\cdot}]_w^2 \qquad (3.43)$$

In contrast to Eq. (3.35), this expression contains the desorption constant $K_d = K_0 S/v$ [s^{-1}], removing the precondition that the rate of radical exit be proportional to the latex particle surface area. Assuming that the radical absorption rate into polymer particles is proportional to $[R^{\bullet}]_W$ and substituting for $R_i = K_a\,[R^{\bullet}]_W$ and multipli-

cation by $\left(\frac{v}{K_{\mathrm{tp}} N_{\mathrm{p}}}\right)$ and making the following substitutions:

$$\alpha = \frac{R_{\mathrm{i}}\, v}{K_{\mathrm{tp}}\, N_{\mathrm{p}}}\,; \quad \alpha' = \frac{R_{\mathrm{i,\,w}}\, v}{K_{\mathrm{tp}}\, N_{\mathrm{p}}}\,;$$
$$m = \frac{K_{\mathrm{d}}\, v}{K_{\mathrm{tp}}}\,; \quad Y = \frac{2 N_{\mathrm{p}}\, K_{\mathrm{tp}}\, K_{\mathrm{tW}}}{K_a^2\, v}$$

gives

$$\alpha = \alpha' + m\bar{n} - Y\alpha^2 \tag{3.44}$$

where Y is a dimensionless group.

Equations (3.41) and (3.44) permit calculation of $\bar{n}$ as a function of a', m, Y. The results for $Y = 0$ (i.e., negligible termination in the water phase) are shown in Figure 54. It is apparent that there is a rather large range of parameter values (α' and m) for which $\bar{n} < 0.5$; this is discussed further in [640] and [597, p. 559 ff].

Figure 54. Average number of radicals $\bar{n}$ per latex particle, assuming interparticle termination and a negligible amount of termination in the aqueous phase ($Y = 0$), calculated by using Equations (3.41 and 3.44) [640]

The number of radicals in a polymer particle clearly depends on rates of radical entry, desorption, bimolecular termination, and chain transfer. Although radical capture efficiencies by polymer particles can be high [644], efficiencies considerably below 100 % have been observed [645]. Brooks [644] has presented general expressions for radical absorption rates which account for reabsorption and give capture efficiencies less than 100 %. Various experimental techniques for the measurement of desorption rates have been employed [645–647]. Lichti et al. [648] obtained significantly enhanced desorption rates from polystyrene particles containing soluble hydrocarbon diluents. It has been suggested that in some systems desorbed radicals cross-terminate in the water phase and are not reabsorbed. Nomura et al. [649] used the pseudokinetic rate constant method to develop expressions for $\bar{n}$ for binary copolymerizations that follow the terminal model. Nomura et al. [650] also observed that the extent of Stage I (particle nucleation stage) could be lengthened by radical desorption.

Mechanism of Particle Formation. As emulsion polymerization always involves a certain amount of monomer in the aqueous phase, and for this reason all the routes depicted in Figure 55 represent possible reactions of the radicals or radical ions that form in the water phase by initiator decomposition:

1) Entry into micelles, which are then transformed into latex particles
2) Propagation within the aqueous phase until a specific critical degree of polymerization P_{cr} is reached, at which point the growing macroradical precipitates to form a latex particle
3) Entry into an existing monomer droplet, which is converted into a latex particle
4) Entry into an existing latex particle, which is then subject once again to propagation (seed polymerization)

Figure 55. Possible radical reactions leading to particle formation during emulsion polymerization (schematic)

With all of these reactions, newly formed particle surface area must somehow be stabilized, either by emulsifier or through the charge originally present on the radical ion, which usually remains at the surface of the particle as the end group of the resulting polymer. If the available degree of stabilization is insufficient, the interfacial area will decrease by coagulation (or flocculation) until a point is reached at which the charge carriers present once again permit stabilization.

Depending on the nature of the rate-determining step, the rate of absorption of radicals into particles or micelles may be proportional to the particle radius, surface area, or volume. Latex particles and micelles can also differ in their capture efficiencies, and differences may even be observed between various latex particles as a result of differences in size, surface charge, and concentration of monomer and radicals [643].

In principle, the various reaction paths in Figure 55 may compete with each other, in which case the system is extremely complex. It is often possible in practice to select reaction conditions that cause one particular pathway to dominate. Further elaboration of the theory is frequently based on assumptions which led to one mechanism being dominant in polymer particle formation. Smith and Ewart [623] followed the Fikentscher – Harkins theory in assuming that latex particles form only as a result of the entry into an emulsifier micelle of a radical formed in the aqueous phase. Particle formation would then continue until the total surface area of the latex particles A_p corresponds exactly to the interface-covering capacity of the emulsifier $a_s \cdot$ [S] minus the area of monomer droplets. A correction for emulsifier dissolved in the water should also be made. In this expression [S] is the emulsifier concentration and a_s is the emulsifier covering capacity per unit of emulsifier (per mole or gram). Based on this assumption, two limiting cases can be described, in each of which it is further assumed that $\bar{n}$ = constant and $[M]_p$ = constant, and that the polymer particles grow with a constant volumetric growth rate, $dv/dt = \mu$ = constant.

Model 1) All of the radicals formed in the water phase by initiator decomposition enter micelles, so that the rate of formation of polymer particles equals the rate of generation of radicals.

$$\frac{dN_p}{dt} = R_{i,w} \tag{3.45}$$

at time $t = t_1$, where $A_p = a_s \cdot$ [S], it follows that

$$t_1 = \frac{0.53}{\mu^{2/5}} \left(\frac{a_s\,[S]}{R_{i,w}} \right)^{3/5} \tag{3.46}$$

Consequently, $N_p = R_{i,w} \cdot t_1$ and

$$N_p = 0.53 \left(\frac{R_{i,w}}{\mu} \right)^{2/5} (a_s\,[S])^{3/5} \tag{3.47}$$

This approximation leads to an upper limit for N_p, because even during Stage I some radicals enter existing polymer particles.

Model 2) Latex particles and micelles absorb radicals at a rate proportional to their current interfacial areas A_p and A_m. The rate of particle formation is therefore

$$\frac{dN_p}{dt} = R_{i,w} \left(1 - \frac{A_p}{a_s\,[S]} \right) \tag{3.48}$$

and it follows that

$$N_p = 0.37 \left(\frac{R_{i,w}}{\mu} \right)^{2/5} (a_s\,[S])^{3/5} \tag{3.49}$$

where μ is the volume growth rate of the latex particles.

Table 4. Influence of various parameters on the number of particles N_p, the overall rate of reaction R_p, and degree of polymerization P_N [612]

Parameter	N_p	R_p	P_N^*
Surfactant concentration [S]	$\sim [S]^{3/5}$	$\sim [S]^{3/5}$	$\sim [S]^{3/5}$
Initiator concentration [I]	$\sim [I]^{2/5}$	$\sim [I]^{2/5}$	$\sim [I]^{-3/5}$
Temperature	$E_N = 2/5\,(E_d - E_P)$	$E_R = E_P + E_N$	$3/5\,(E_P - E_d)$

$*$ Ignoring chain transfer

Table 4 illustrates the interdependency of the number of particles N_p, the rate of polymerization R_p, and the degree of polymerization P_N based on Equations (3.42) and (3.47) or (3.49) [612]. The relationships have been confirmed experimentally over wide ranges of the relevant variables for such relatively water-insoluble monomers as styrene, butadiene, isoprene, and chloroprene [651–658]. By contrast, other relationships are found to apply in certain situations,

especially in the case of more soluble monomers with large transfer-to-monomer rate constants, including vinyl acetate and vinyl chloride [640], [642], [659–664]. Even in the case of styrene it is not possible to explain all the experimental results on the basis of the Smith – Ewart theory. If particle formation were to conform to Model 1, then at the end of Stage I, each latex particle would contain precisely one radical, i.e., $\bar{n} = 1$ [665]. In addition the molecular mass of the polymer chain in a particle nucleated near $t = 0$ would be extremely large at the end of Stage I. For Model 2, $\bar{n} = 0.67$ at the end of Stage I [628]. Since $\bar{n} = 0.5$ during Stage II, R_p must peak at the end of Stage I. However, no such maximum has been observed with styrene. Moreover, N_p calculated by using Equations (3.47) or (3.49) often exceeds observed values by a factor of 2 – 3. These discrepancies can be rationalized by assuming that latex particles are more efficient at capturing radicals than micelles [665], [666]. Some particle coagulation would also reduce the discrepancy. If radicals formed in the aqueous phase can enter either micelles or latex particles, the condition for radical balance assures that

$$\frac{d\,[R^{\cdot}]}{dt} = R_{i,w} - K_1\,[M_i]\,[R^{\cdot}] - K_2 N_p\,[R^{\cdot}] \tag{3.50}$$

where $[M_i]$ is the micelle concentration. Assuming a stationary state is valid, one obtains

$$[R^{\cdot}] = \frac{R_{i,w}}{K_1\,[M_i] + K_2 N_p} \tag{3.51}$$

Particle formation should only occur after the entry of a radical into a micelle, so

$$\frac{dN_p}{dt} = K_1\,[M_i]\,[R^{\cdot}] \tag{3.52}$$

Substitution of Equation (3.51) into (3.52) gives

$$\frac{dN_p}{dt} = \frac{K_1\,[M_i]\,R_{i,w}}{K_1\,[M_i] + K_2 N_p} = \frac{R_{i,w}}{1 + \frac{K_2 N_p}{K_1\,[M_i]}} = \frac{R_{i,w}}{1 + \frac{\varepsilon N_p}{[S]}} \tag{3.53}$$

where $[S]/[M_i] = M_m$ is the aggregation number for emulsifier molecules in micelles (in many cases, $M_m \approx 100$); $K_2 N_p / K_1\,[M_i] = \varepsilon N_p/[S]$ is the ratio of the rate of entry into latex particles versus micelles, and $\varepsilon = (K_2/K_1) M_m$ characterizes the radical capture efficiency of latex particles relative to micelles. For $\varepsilon N_p/[S] \ll 1$, Equation (3.53) is equivalent to Equation (3.45) and Smith – Ewart kinetics are applicable in the form of Equation (3.47).

On the other hand, in the case where $\varepsilon N_p/[S] \gg 1$, there is a somewhat different dependency, with $N_p \sim (R_{i,w})^{2/7}$ and $N_p \sim [S]^{5/7}$. To obtain agreement between calculated and experimental N_p, it is necessary to introduce the values $\varepsilon = 1.3 \times 10^5$ for styrene [666] and $\varepsilon = 1.2 \times 10^7$ for vinyl acetate [667]. This is explained by assuming that radicals exit very rapidly from very small latex particles as well as micelles – so rapidly that they do not have sufficient time to propagate to the extent required for insolubility in the water phase. HANSEN and UGELSTAD [597, p. 556, 602 ff], [668] have applied Danckwerts theory of diffusion with homogeneous reaction [669] to this problem. The rate of absorption by latex particles that already contain a radical is significantly larger than that of latex particles and micelles containing no radicals, because the rate of termination between two radicals is much higher than the rate of propagation. Termination by combination with a second radical normally leads to molecules that are no longer able to desorb due to having exceeded the critical degree of polymerization P_{cr}.

In the derivation of Equations (3.47) and (3.49) the volumetric growth rate μ of a latex particle, given by

$$\mu = \frac{dv}{dt} = \frac{K_p \varphi_m}{N_A\,(1 + \varphi_m)} \cdot \frac{\varrho_m}{\varrho_p} \cdot \bar{n} \tag{3.54}$$

was considered constant since $\bar{n}$ was taken to be a constant, independent of the latex particle age. This assumption is no longer valid when Case 1 kinetics apply, and $\bar{n}$ increases with particle growth. Reference [643] has therefore adopted the following general relationship for the rate of particle formation:

$$\frac{dN_p}{dt} = R_i \cdot \frac{\delta N_M\, r_M^{\chi}}{\delta N_M\, r_M^{\chi} + N_M\, r_p^{\chi}} \tag{3.55}$$

where N_M is the number of micelles, r_M is the micelle radius, and r_p is the particle radius, χ (= 1, 2, 3) is the exponent that characterizes the dependence of the capture rate on the radii of the micelles and polymer particles, and δ is an efficiency factor for the capture of radicals by micelles relative to polymer particles. This in turn is a function of the factor ε in Equation (3.56):

$$\delta = \frac{M_m}{\varepsilon}\left(\frac{r_p}{r_M}\right)^{\chi} \tag{3.56}$$

Neglecting termination in the aqueous phase, Equation (3.43) is transformed into

$$R_i = R_{i,w} + K_d\,\bar{n}\,N_p \tag{3.57}$$

and Equations (3.55) and (3.57) then lead to

$$\frac{dN_p}{dt} = \frac{R_{i,w} + K_d\bar{n}N_p}{\left[1 + \frac{N_p}{\delta N_M}\left(\frac{r_p}{r_M}\right)^{x}\right]} \tag{3.58}$$

Assuming that only monomer transfer radicals are capable of desorbing from latex particles, HANSEN and UGELSTAD [643] constructed a balance equation for the formation and disappearance of latex particles containing a single monomer transfer radical, and then proceeded to solve it under the assumption of steady state. One can then assume either that desorbed radicals do not add monomer in the aqueous phase, and instead simply wander from one particle to another, or that such radicals do in fact add at least one monomer molecule in the aqueous phase. In the latter case, no monomer transfer radicals absorb into the latex particles, and the chain-transfer reaction becomes the sole source of monomer radicals in the particles. For further details refer to the original article [643]. What finally results from these calculations is a set of curves representing the number of particles N_p as a function of the emulsifier concentration [S] and the rate of initiation $R_{i,w}$ as shown in Figure 56 for various monomer types, assuming there is no chain transfer to monomer in the aqueous phase. Other graphs of interest corresponding to various values of δ and χ may be found in [643]. These curves serve as a basis for the rule that the sum of the orders with respect to [S] or [I] (or $R_{i,w}$) for styrene, methyl methacrylate, vinyl acetate, or vinyl chloride is always in the vicinity of 1.0. Stated more generally

$$N_p \sim [S]^z\,, N_p \sim [I]^{1-z} \tag{3.59}$$

where $0.6 < z < 1.0$. If desorption and reabsorption dominate (total radical entry rate $\gg R_{i,w}$) $z = 1.0$; if there is no desorption of radicals, $z = 0.6$ (usual value for styrene). The actual value of z may vary with [S] and [I]. If all other variables are held constant, then an increase in [S] or [I] leads to an increase in the order z relative to [S] or [I], while the order with respect to the variable that is held constant decreases [643].

In the case of monomers that are significantly more soluble in water than styrene, it is also necessary to take into account the fact that latex particles can be formed by homogeneous nucleation in the aqueous phase [655]. However, Equations (3.47) and (3.49) based on the Smith – Ewart theory (which, incidentally, do not explicitly refer to particle formation from micelles) remain valid even when homogeneous nucleation is significant [670]. The rate of particle formation then becomes equal to either $R_{i,w}$ (for Model 1 and Eq. 3.47) or $R_{i,w}$ minus the rate of radical capture by previously formed latex particles (Model 2 and Eq. 3.49). The volumetric growth rate μ is taken here to be constant, and particle nucleation ceases when the total latex particle surface area corresponds to a_s [S]. The concentration of free emulsifier should at this point be somewhat lower than the CMC.

FITCH and coworkers have developed the theory of homogeneous particle nucleation further [606, pp. 73 – 102, 103 – 116], [671–675]. With [S] < CMC, a radical produced in the aqueous phase by initiator decomposition continues to grow in this phase until it is either absorbed by an existing latex particle or a specific critical degree of polymerization P_{cr} has been exceeded,

whereupon the macroradical precipitates and forms a primary polymer particle. In this case the rate of particle formation is described by

$$\frac{dN_p}{dt} = R_{i,w} - v_c \tag{3.60}$$

A steady-state (where $R_{i,w} = v_c$) is reached at $t = t_s$, which means that the number of polymer particles nucleated is given by

$$N_p = \int_0^{t_s} (R_{i,w} - v_c)\, dt \tag{3.61}$$

originally, the rate of capture v_c was taken to be [628], [673].

$$v_c = R_{i,w} (N_p \pi r^2)\, L \tag{3.62}$$

where L is the length of the path traversed by the growing radical from its point of origin to the point where it precipitates as a primary particle (collision theory). This proposal has been subjected to criticism [493, pp. 163 ff], [629] and the expression

$$v_c = 4\pi D_{op} C_S N_p r \tag{3.63}$$

where D_{op} is the mean diffusion coefficient for oligomeric radicals and latex particles in the aqueous phase and C_S is the concentration of oligomeric radicals in the same phase in fact provides a better fit than Equation (3.62) to experimental data on particle nucleation in the presence of seed particle [675]. The effectiveness of seed particles in capturing oligomeric radicals before they grow and precipitate to form new particles corresponds not to $N_p r^2$ but rather to $N_p r$. Hansen and Ugelstad [597, pp. 556, 602 ff], [643] have proposed a model for radical capture that takes into account not only the possibility of radical desorption, but also the electrostatic repulsion between radicals and particles.

One practical application of these considerations relates to stepwise seed polymerization as a means of preparing uniformly large (monodisperse) latex particles [676], [677], in which the key consideration is keeping v_c as large as possible; i.e., preventing the formation of new polymer particles.

Figure 57. Number of particles N_p as a function of conversion in the emulsion polymerization of methyl methacrylate with sodium dodecylsulfate as emulsifier [606, pp. 73 – 102]
Concentrations in mol/L: $[S_2O_8^{2-}] = 7.35 \times 10^{-4}$, $[HSO_3^-] = 1.14 \times 10^{-3}$; $T = 30\,°C$

In certain formulations (e.g., in the absence of emulsifier, or where the emulsifier concentration is very low) charge density on the polymer particle surface is insufficient to stabilize the resulting particles. Moreover, with relatively soluble monomers such as methyl acrylate the interfacial tension is especially low, and emulsifiers are apparently less strongly adsorbed. The relationships here are further complicated by the fact that particles tend to coagulate until the surface area has been reduced (surface charge density has increased) sufficiently to restore stability, a process for which experimental evidence also exists [590, pp. 292 ff], [629], [678]. Figure 57 shows experimental data for the production of particles by homogeneous nucleation, in which methyl methacrylate was polymerized with various rates of initiation $R_{i,w}$ and sodium dodecyl sulfate concentrations ranging from zero to the CMC. With increasing conversion the number of particles passes through a maximum before falling to a constant value. The conversion at this maximum as well as the final constant number of polymer particles is lower for lower $R_{i,w}$ values and lower emulsifier concentrations. Very sim-

ilar results have been obtained with ethyl acrylate [679]. Electron micrographs of the resulting polyacrylate latex particles after etching with O_2 clearly show that they were formed by coagulation of a large number of smaller primary particles.

If limited coagulation (or flocculation) occurs, it is necessary to also take into account the rate of flocculation v_f, transforming Equation (3.60) into

$$\frac{dN_p}{dt} = R_{i,w} - v_c - v_f \tag{3.64}$$

The Smoluchowski theory [680] can be used to calculate the flocculation rate v_f [674].

If to an anionic or cationic emulsifier there is added a small amount of a straight-chain alcohol whose chain length corresponds at least to that of the emulsifier, then emulsification leads to an especially stable emulsion consisting of many very small monomer droplets. Polymerization of such an emulsion with an oil- or water-soluble initiator can, in an appropriate formulation, lead to almost total adsorption of the emulsifier on the surface of the monomer droplets. Since the number of micelles is no longer large compared to the number of monomer droplets, polymerization occurs partially or even principally within the monomer droplets. The consequence is a bimodal distribution of polymer particle sizes, where small particles formed in the aqueous phase are accompanied by large particles whose origin is in the monomer droplets. In the limiting case, the size distribution of the latex particles corresponds almost exactly to that of the original monomer droplet size distribution [681], [682]. These relatively large latex particles may contain considerably more than one radical and the observed polymerization kinetics are similar to those for homogeneous bulk polymerization [683], [684]. This therefore represents a transition toward suspension bead polymerization.

An emulsion polymerization in which polymerization occurs in both latex particles (formed from micellar or homogeneous nucleation) and monomer droplets is called miniemulsion polymerization (a term coined by the Lehigh University Group). For such systems bimodal PSD as well as polymerization rates have been both measured and predicted [685–687].

Song and Poehlein [688–690] have developed new approaches to modeling homogeneous nucleation for monomers having a range of water solubility. They account for the variation of the critical chain length for precipitation with concentration, and for sparingly soluble monomers suggest that oligomers generated in the water phase form micelles which are then stung by a radical to generate polymer particles. They also showed that the number of polymer particles N_p increases slowly with emulsifier concentration [S] below the CMC, where homogeneous nucleation is dominant, but rapidly increases above the CMC due to micellar nucleation. Others have concluded that micellar nucleation is dominant even for monomer with appreciable water solubility [691].

Radical scavengers (e.g., O_2 and monomer inhibitors such as *tert*-butyl catechol) can have interesting effects on the number of polymer particles formed and $\bar{n}$. Radical scavengers have been classified as water soluble and monomer (organic) soluble [692], [693]. Oxygen, which dissolves in water, monomer droplets, micelles, and polymer particles, mainly influences the initiation of particle nucleation. Oxygen dissolved in the aqueous phase reacts rapidly with primary radicals, preventing particle nucleation. This results in an induction period in which no polymerization occurs. The induction period ends when the oxygen content of the aqueous phase has been reduced to an almost indetectable level. After the induction period, apart from usually a minor loss of initiator, the polymerization takes its normal course. However, in the presence of, say, *tert*-butyl catechol (an oil-soluble inhibitor) in the micelles and polymer particles, polymer particles are nucleated, but $\bar{n}$ can be very low due to radicals reacting with inhibitor. This reduces the volumetric growth rate μ and hence a larger number of polymer particles are nucleated (refer to Equations (3.47), (3.49), and (3.54). Once the organic-soluble inhibitor has been consumed, the polymerization rate recovers but to a rate higher than originally expected in the absence of the inhibitor. This phenomenon can cause low-frequency oscillations in reactor trains when inhibitor contents in monomer recycle streams vary and potential safety problems for all reactor types (heat generation rate may be excessive).

3.3.3.4.2. Physicochemical Parameters of Dispersions

This section treats some properties of dispersions that can be unambiguously described in terms of physiochemical quantities. In addition to these, applications technology makes use of a number of other characteristics, primarily empirical quantities and tests, [694], [695].

Molecular Mass Distribution of Linear Homopolymer Chains. In emulsion polymerization, chain transfer to monomer is more important than in homogeneous bulk polymerization because bimolecular termination rates for a given polymerization rate are generally lower for emulsion polymerization. This is why it is possible to obtain high molecular mass at high polymerization rates in these systems. When transfer to monomer is dominant in controlling molecular mass development, the process type is irrelevant and molecular masses of linear chains depend solely on polymerization temperature. Therefore, equations developed in Section 2.2 for bulk and solution polymerization in homogeneous media may be used to calculate molecular mass distributions. A useful experimental test to determine whether chain-transfer reactions to small molecules (monomer or chain-transfer agent) are dominant in producing polymer is to change the concentration of initiator by several fold. If molecular masses decrease with increasing initiator concentration then a significant fraction of polymer chains are formed by bimolecular termination. However, if polymer molecular mass is independent of initiator concentration, then chain-transfer reactions are dominant in producing polymer chains [696].

When termination reactions are significant in molecular mass development, the calculation of MWD and average molecular masses is generally not straightforward. There are several complicating factors. Firstly, the MWD depends on the polymer particle size distribution, which is difficult to predict in commercial latex systems. Even if the PSD were known one would still need to know the mechanism by which radicals enter particles. Attempts to predict the PSD have been made by using population balance methods [697–700].

Experimental verification of these PSD predictions is lacking in most cases. The molecular masses depend on radical entry rate per particle, which in turn is some unknown function of particle size and number. For the special case of a monodisperse latex the radical entry rate is known, however, and this case can be easily treated when termination is instantaneous (rate of radical entry is much smaller than the rate of termination in the polymer particle; or in other words two radicals cannot coexist in a polymer particle). This is true for Case 2 kinetics ($\bar{n} = 1/2$). An expression is now derived which describes molecular mass development for this special case. Transfer to monomer and to chain-transfer agent are included in the analysis.

Consider an oligomeric radical in a polymer particle. The probability that this radical adds r monomer molecules and then terminates either by chain transfer to monomer or chain-transfer agent T or by instantaneous termination with a new oligomeric radical which enters the particle from the aqueous phase is given by $\varphi^{r}\ (1-\varphi)$, where

$$\varphi = \frac{K_{\mathrm{p}}\,[\mathrm{M}]_{\mathrm{p}}}{K_{\mathrm{p}}\,[\mathrm{M}]_{\mathrm{p}} + K_{\mathrm{fm}}\,[\mathrm{M}]_{\mathrm{p}} + K_{\mathrm{fT}}\,[\mathrm{T}]_{\mathrm{p}} + \left(\frac{R_{\mathrm{i,w}}}{N_{\mathrm{p}}}\right) N_{\mathrm{A}}} \tag{3.65}$$

The instantaneous weight chain length distribution $W(r,t)$ is therefore given by

$$W\ (r,t) = \frac{r\ (1-\varphi)\ \varphi^{r}}{\int_{0}^{\infty} r\ (1-\varphi)\ \varphi^{r}\mathrm{d}r}$$

$$= r\ (1-\varphi)^{2} \exp\left(-\ (1-\varphi)\ r\right) \tag{3.66}$$

where K_{fm} and K_{fT} are rate constants for chain transfer to monomer and chain-transfer agent T.

Equation (3.66) is the most probable distribution, with number- and weight-average degrees of polymerization given by

$$P_{\mathrm{N}} = \frac{1}{(1-\varphi)} \tag{3.67}$$

$$P_{\mathrm{W}}/P_{\mathrm{N}} = 2 \tag{3.68}$$

These expressions should be valid for systems such as styrene and methyl methacrylate when Case 2 kinetics apply and the PSD is quite narrow. It is worth mentioning that in bulk polymerization of styrene at low conversions the polydispersity ($P_{\mathrm{W}}/P_{\mathrm{N}}$) is 1.5 because bimolecular termination by combination produces most of

the polymer chains. A polydispersity of 2 in emulsion polymerization is due to the fact that when termination is instantaneous, termination by combination acts like termination by disproportionation. In fact the polydispersity (for polymer produced instantaneously) obtained in emulsion polymerization of any monomer type will always be equal to or greater than that in homogeneous solution or bulk polymerization. Equations (3.66) – (3.68) apply to an essentially monodisperse latex. For polydisperse PSD it is clear that instantaneous molecular mass properties will be broader as will the MWD of polymer accumulated in the polymer particles over polymerization times of several hours. For most commercial recipes, chain-transfer agents are used to control molecular mass development. In these cases, the MWD is independent of the PSD, and molecular mass calculations for both polymer produced instantaneously and accumulated polymer are straightforward. φ is then equal to $K_{\mathrm{fT}}\,[\mathrm{T}]_{\mathrm{p}}/K_{\mathrm{p}}\,[\mathrm{M}]_{\mathrm{p}}$, the instantaneous weight chain length distribution is again given by Equation (3.66), and the MWD of the accumulated polymer for a batch reactor is given by Equation (3.69)

$$\bar{W}\,(r,t) = \frac{\int_0^t W\,(r,t)\,R_{\mathrm{p}}\mathrm{d}t}{\int_0^t R_{\mathrm{p}}\mathrm{d}t} \tag{3.69}$$

Several theoretical papers dealing with MWD development in emulsion homopolymerizations are available [701–705]. The problem has now been fully solved [706], [707] for the case when two or more radicals can coexist in a polymer particle (zero – one – two, systems). When the PSD is broad, the population balance equations for particle size and molecular mass are coupled, requiring numerical solution of a large set of partial differential equations [708].

Polymer Chains with Long-Chain Branching. Long-chain branching and cross-linking can occur as a result of chain transfer to polymer and by addition of polymeric radicals to terminal and pendant double bonds. The dimensionless groups which are relevant in polymer chain modification by these reactions are

$$\frac{\bar{F}_1 K_{\mathrm{fp}} Q_1}{K_{\mathrm{p}}\,[\mathrm{M}]_{\mathrm{p}}},\ \frac{K_{\mathrm{p}}^{*} Q_0}{K_{\mathrm{p}}\,[\mathrm{M}]_{\mathrm{p}}}\ \text{and}\ \frac{\bar{F}_2 K_{\mathrm{p}}^{*} Q_1}{K_{\mathrm{p}}\,[\mathrm{M}]_{\mathrm{p}}}$$

where K_{fp}, K_{p}^{*} are chain transfer to polymer rate constant and rate constant for the addition of polymeric radicals to terminal and pendant double bonds, respectively; Q_1 is the number of moles per liter of monomer molecules chemically bound to polymer chains (proportional to grams per liter of polymer); Q_0 is moles of polymer per litre which have a terminal double bond; $\bar{F}_1$ is the fraction of monomer molecules in the polymer chains which have an extractable atom; $\bar{F}_2$ is the fraction of monomer molecules in the polymer chains which have a pendant double bond. As these dimensionless groups increase in value, long-chain branching and cross-linking (cross-linking density and gel/sol ratio) increase. These groups increase with monomer conversion and usually increase with polymerization temperature. Long-chain branching and cross-linking reactions are more important in emulsion polymerization than in homogeneous solution, bulk, and suspension polymerization because even at the birth of a latex polymer particle, the concentration of polymer in the particle is large [709]. Chain branching, cross-linking, and gel formation are undesirable for the manufacture of cold SBR and NBR by continuous emulsion polymerization. To minimize long-chain branching, three important features of plant design are:

1) A large number of back-mixed reactors in series (this gives a narrow residence-time distribution which is desirable for low levels of branching)
2) The final conversion is kept rather low (ca. 63 % monomer conversion for cold SBR)
3) The polymerization temperature (ca. 5 °C for cold SBR) is kept low to reduce $K_{\mathrm{fp}}/K_{\mathrm{p}}$ and $K_{\mathrm{p}}^{*}/K_{\mathrm{p}}$

When carrying out semi-batch emulsion polymerization, extending the addition time of monomers lowers $[\mathrm{M}]_{\mathrm{p}}$, and this can lead to higher levels of long-chain branching and cross-linking.

Linear and Branched Copolymer Chains. For such calculations, it is recommended that the pseudo-kinetic rate constant method be employed. Emulsion copolymerizations can be successfully modeled (calculations of polymerization rate, chain microstructure, molecular mass,

and long-chain branching and cross-linking) by application of the pseudo-kinetic rate constant method [417], [649], [710] and properly accounting for changes in chemical and physical properties during the course of polymerization [711–713].

Copolymer composition is usually controlling semi-batch operation [357], [405], [714], [715]. The composition of polymer particles depends on the thermodynamic compatibility of polymer chains and is not always spatially uniform. Core/shell morphology, which is often the planned particle morphology for specialty products, can be effected by grafting and cross-linking reactions as well as compositional drift [715–718]. Special end use properties can be obtained by controlling morphology [719], [720]. The morphology of latex particles is also a function of the mechanism of particle formation. Limited coagulation (flocculation) leads to latex particles composed of a number of not entirely fused smaller primary particles. Such particles are often not smooth and spherical, displaying a rather rough surface and an irregular lumpy or "potato-like" shape [721].

Polymer Particle Size Distribution. In general, the PSD is narrower the lower the conversion at the end of Stage 1 is relative to the final conversion at the end of the polymerization. In the limiting case of stepwise seed polymerization, no new polymer particles are produced, even though a very high monomer conversion is reached, resulting in larger latex particles that are nearly monodisperse in PSD [676], [677]. A semiquantitative calculation [590, p. 275 ff] based on Smith – Ewart Case 2 kinetics shows that PSD narrows with increasing monomer/water ratio, as well as with increasing temperature, increasing initiator concentration in the aqueous phase, and decreasing emulsifier concentration [S]. Experiments involving styrene have confirmed these predictions. Quantitative calculations are also in good agreement with experiment [606, pp. 153 – 161] for styrene emulsion polymerization. A more comprehensive population balance model which accounts for coagulation in the seeded emulsion polymerization of vinyl chloride has been developed [722]. The predicted bimodal distributions of particle size are in good agreement with experimental data.

GIANETTI [699] in a theoretical study of the evolution of PSD in Stage 2 has reviewed the more important theoretical studies and discussed their limitations. The results obtained represent a generalization of previous theories in that

1) A comprehensive description for monomer systems which conform to zero – one kinetics has been made
2) The contribution of latex particles having more than one growing radical has been properly accounted for
3) Bimolecular termination has been explicitly included in the model (at least where mutual annihilation of two growing chains is not the main termination reaction)
4) General expressions for the time evolution of the cumulants of the PSDs (both in the transient and nontransient case) have been determined

GIANETTI's solutions not only revise theoretical misinterpretations which appeared in the literature, but also allow rate coefficients to be extracted with more precision from reliable experimental data. In this connection it has been shown that rate coefficients obtained from experimental PSD data are in good agreement with values found by using dilatometry to measure rates of polymerization. Recent interest in analyzing the experimental time evolution of PSD is due mainly to the possibility of determining kinetic rate constants with a small confidence interval [602], [723]. According to GIANETTI's solutions PSD and kinetic data are not independent of each other at steady state (in other words, if a certain volume dependence for the entry rate constant is assumed, from the analysis of an experimental PSD one must find the same volume dependence for the exit rate constant). Apparently, PSDs for systems with $\bar{n} \leq 1/2$ are insensitive to assumptions about the mechanisms of radical entry and exit. In this connection, a new approach based on the effect of PSD on MDW has been proposed [724]. In fact, a similar approach was proposed much earlier by DEGRAFF and POEHLEIN [725]. A CSTR was used to obtain a broad PSD for styrene emulsion polymerization, and assuming that radical capture was according to the collision theory (capture rate $\sim r^2$), a polydispersity of 4.84 was calculated for the MWD, DEGRAFF and POEHLEIN's MWD measurements showed that the molecular mass averages $\bar{M}_N$ and $\bar{M}_W$

were independent of mean residence time and that the polydispersity was ca. 3. The discrepancy between theory and experiment may be due to any number of possibilities, including:

1) Perhaps the collision model is not valid (try the diffusion model)
2) Larger latex particles may not obey Case 2 kinetics
3) Transfer to monomer may not be insignificant

Similar experimental data were found for continuous emulsion polymerization of styrene in a CSTR [726]. Simultaneous growth of latex particles by polymerization and coagulation may occur at various stages in emulsion polymerization [688–690], [723], [727–730]. For the calculation of PSD in the emulsion polymerization of vinyl chloride, it may be necessary to account for coagulation [731], [732].

The extent of coverage of the particle surfaces by emulsifier is an important factor in the stability of a dispersion. For example, this coverage should not be too large if the polymer is to be later recovered by controlled coagulation. The surface coverage is evaluated in a detergent titration [733], [734], in which the amount of emulsifier that must be added to give total monomolecular coverage of the surface is measured. Total coverage is indicated, for example, by the point where additional emulsifier no longer lowers the surface tension (surface tension remains constant after micelles are formed). If the surface coverage required for particle stability is known, emulsifier can be added during Stage II to maintain stability but not form new micelles with the danger of nucleating a second family of particles. More is involved here than simply the adsorption of an emulsifier on the particle surfaces, however. The majority of the hydrophilic end groups on polymer molecules also tend to migrate to the interface (e.g., $-OH$, $-SO_4$, $-COOH$), thereby contributing to stabilization of the polymer particles. A comparable effect is achieved by the addition of small amounts of hydrophilic comonomers (e.g., acrylic or methacrylic acid), which polymerize preferentially at the particle surface [721].

The minimum film-forming temperature of a polymer is the lowest temperature at which a dispersion can be converted into an integral film on a surface by evaporation of the water. This normally corresponds approximately to the glass transition temperature T_g of the polymer and is one of the most important application parameters of a polymer dispersion. Copolymerization of monomers whose homopolymers have a range of glass transition temperatures makes it possible to achieve desired values for both the glass temperature and the minimum film-forming temperature. The glass transition temperature $[T_g]$ of the copolymer can be calculated by using the equation

$$T_g = \frac{W_1 T_{g1} + K W_2 T_{g2}}{W_1 + K W_2} \text{ with } K = \frac{\Delta\alpha_1}{\Delta\alpha_2} \tag{3.70}$$

where W_1 and W_2 are mass fractions of monomers 1 and 2 in the copolymer, T_{g1} and T_{g2} are the glass transition temperatures of the corresponding homopolymers, and $\Delta\alpha_1$ and $\Delta\alpha_2$ are the differences between the thermal expansion coefficients above and below T_g (melt and glass) for the two homopolymers.

3.3.3.4.3. Inverse Emulsion Polymerization

In inverse emulsion polymerization, a hydrophilic monomer is dissolved in water, emulsified in a continuous hydrophobic oil phase with a water-in-oil emulsifier, and polymerized by using an oil- or water-soluble initiator. The product is a latex consisting of very small polymer particles, swollen with water and suspended in an oil continuous phase. The emulsified monomer droplets are also very small, and they may serve as the source of some of the latex particles (a form of miniemulsion polymerization). The overall rate of polymerization is significantly higher here than in the corresponding solution polymerization. This observation strongly supports the idea that what is occurring is a true inverse emulsion polymerization rather than an inverse suspension polymerization. When oil-soluble initiators are used with aromatic continuous phases the kinetics have been shown to resemble those of emulsion polymerization [576], [577], [735] with the locus of nucleation of particles in inverse micelles. However, when paraffinic oil continuous phases are used, as is most common commercially, the locus of particle nucleation and polymerization is in the

monomer droplets and the process is properly called inverse suspension polymerization (the term microsuspension is often used because the monomer droplets are nominally 1 μm in diameter) [575]. This has been verified by dynamic light scattering measurements which failed to detect inverse micelles and indicated a constant particle size throughout the polymerization [578–580]. Reviews of polymerization in inverse emulsions and microemulsions are available [736–738]. Inverse microsuspension polymerization has been used to study the kinetics of polymerization of acrylamide with cationic comonomers (quaternary ammonium cationic monomers) [739].

Water-in-oil emulsions of high molecular mass polyacrylamide and acrylamide copolymers (anionic and cationic) are particularly useful as flocculating agents in sewage treatment and as retention aids in papermaking. At the present time inverse emulsion and microsuspension polymerization is the only technology for the large-scale production of very high molecular mass polymers in a liquid-like form that affords a convenient suspension viscosity, high solids content, and easy phase inversion during application [740–742].

3.3.3.4.4. Semi-Batch Emulsion Polymerization

In semi-batch polymerizations, water, monomers, initiators, and emulsifiers may be added to a reactor over a time period which is comparable to the total polymerization time (usually over several hours). Several feed policies have been employed. For example, a starting mixture of water, emulsifier, and initiator is first prepared, usually also containing a portion of the monomer; the remaining monomer (often together with initiator) is added during the course of polymerization (monomer feed) [743]. With another procedure, the polymerization is begun in a portion of the total batch, the rest being fed into the reactor gradually after the onset of polymerization in the form of a monomer emulsion (emulsion feed), although the composition of the feed may well differ somewhat from the material used to initiate the process [744].

Semi-batch processes are intermediate between batch and continuous polymerization processes. A monomer-feed process based on a very large starter mix resembles more batch processes, whereas an emulsion semi-batch process involving a small initial charge with most of the monomers being fed in during the semi-batch period is more similar to continuous processes. These two semi-batch methods are often mentioned in the patent literature [745]. Their advantages include better control of polymerization and heat-generation rates by appropriate manipulation of feed rates. Moreover, the concentration of unreacted monomer can be minimized (offering a safer process which is less prone to runaway) and cold feed can give higher productivity (less demand for jacket or condenser cooling, for example). In the case of copolymerizations, it is possible to manipulate monomer feeds to control copolymer composition [746–751]. In particular, such methods are often exploited for the purpose of reaching a specific degree of polymerization, particle size, or particle size distribution without changing the overall composition of the copolymer in the latex particles. Adjustment of the process parameters can also have an influence, for example, on the stability of an acrylate dispersion [752–755].

Kinetic studies [756], [757] have shown that, provided the feed rate is not too large, both types of semi-batch polymerization experience a quasi-steady state in which the polymerization rate and feed rate of monomer remain comparable. During the semi-batch feeding period, the concentration of monomer $[M]_p$ is relatively constant and it stays below the saturation concentration predicted by Equation (3.34). The resulting conversion – time curves are linear over a wide range of monomer feed times. Increasing the monomer feed rate causes an increase in $[M]_p$ and according to Equation (3.42) this also leads to increases in both R_p and P_N. Slower feed rates prolong the steady state period, and this should result in a narrower MWD for the polymeric product [757], [758]. Prolonging the monomer feed period lowers $[M]_p$ and raises polymer concentration. For certain types of monomer this can lead to greater long-chain branching and cross-linking [355], [357].

When every ingredient except a reserve portion of the monomer is initially charged to the reactor, the phase ratio of monomer/water differs from the corresponding batch process, but this has no effect on the number of particles nucle-

ated. On the other hand, when polymerization is initiated in a portion of the complete recipe, the number of polymer particles nucleated per unit volume of emulsion may not be the same as for a batch process. Clearly the number of particles nucleated in the initial charge will be much less. If the onset of addition is delayed until some time after polymerization has begun, then Stage I (the nucleation stage) for the initial charge may have been completed. If no further particles are nucleated during the semi-batch feed period, the feed will be entirely directed towards the growth and stabilization of the existing polymer particles. The number of polymer particles is then fewer and their size at the end of the polymerization is larger. Based on the same total recipe, the two semi-batch processes just described can be compared and contrasted as follows:

When the initial charge and the semi-batch feed have the same recipe (composition), fewer (hence larger) latex particles are produced than for the batch process or the semi-batch process with just monomer fed to the reactor over time. If particle formation is avoided during the semi-batch period, then the initial rate of polymerization $R_{p,o}$ and the number of particles nucleated N_p will be proportional to the size of the initial charge.

Assuming particle formation does not occur during the semi-batch feed period, emulsion feed provides a narrower PSD than monomer feed or batch polymerization. If particle formation does occur during emulsion feed, then the PSD becomes broader, and in extreme cases it can be even broader than with the other processes. Particle formation during semi-batch feed can be suppressed by using a larger amount of initial charge and prolonging the time period before semi-batch feed is initiated (i.e., more polymer particles are nucleated and grow larger before semi-batch feed is initiated). Taking the increasing surface area into account also makes it possible to adjust the emulsifier feed so that new polymer particles are not nucleated and no coagulation occurs [759].

As long as the rate of addition of monomer is sufficiently large to keep the polymer particles saturated, then the rate and degree of polymerization for both semi-batch processes are independent of feed rate.

If the monomer concentration falls below its saturation value in the polymer particles (due to slow monomer feed, for example) then the rate of polymerization will equal the monomer feed rate. The rate of polymerization and heat-generation rate will increase with increasing monomer feed rate. The polymerization temperature can therefore be controlled by manipulating the monomer feed rate.

For the control of copolymer composition distribution, various monomer feed policies may be used and equations have been developed to determine the appropriate time-dependent feed rates required [356], [357], [405]. Consideration of molecular mass, long-chain branching, and cross-linking is also possible [357].

3.3.3.4.5. Continuous Emulsion Polymerization

Continuous emulsion polymerization is used particularly where the latex is to be coagulated and the solid polymer recovered. Important examples include the manufacture of styrene – butadiene rubber (cold SBR) [760–762], acrylonitrile – butadiene rubber (NBR) [763], polychloroprene [764], [765], SAN and ABS polymers [766–769], and poly(vinyl chloride) [733], [770]. For products used in latex form, most manufacturers prefer the flexibility associated with batch and semi-batch processes, especially with product lines that are subject to frequent change. Apparently, however, there is also a certain amount of large-scale polymer dispersion manufacture by the continuous process.

Systematic investigations have been carried out on the kinetics and mechanisms of particle formation in continuous stirred-tank or stirred-cascade reactors for styrene [771–781], styrene – butadiene [782], [418], [419], ethylene [783], vinyl chloride [733], [784], [785], vinyl acetate [786–791], methyl methacrylate [786], and methyl acrylate [776]. A tubular reactor has also been analyzed [780] and review articles are available [792], [793] on the general subject of continuous emulsion polymerization.

The most important elements of the theory of emulsion polymerization in a stirred reactor or stirred reactor cascade have been presented by Gerhsberg and Longfield [771]. They began with the Smith – Ewart assumption that latex particles originate with the entry of an oligomeric radical into a micelle, and that

radicals enter both latex particles and micelles according to their surface areas (collision theory, with no distinction between micelles and polymer particles). The following equation then describes the steady state with particle formation rate equal particle outflow rate (Case 2 kinetics apply)

$$\frac{\mathrm{d}N_\mathrm{p}}{\mathrm{d}t} = \frac{R_{\mathrm{i,\,w}}\,A_\mathrm{m}}{A_\mathrm{m}+A_\mathrm{p}} - \frac{N_\mathrm{p}}{\tau} = 0 \tag{3.71}$$

where A_m and A_p are the surface areas per unit volume of latex for micelles and polymer particles and τ is the mean residence time of a single CSTR. The residence-time distribution for latex particles in a CSTR is given by

$$E\,(t)\;\mathrm{d}t = \frac{\mathrm{d}N_\mathrm{p}}{N_\mathrm{p}} = \frac{1}{\tau}\exp\,(-t/\tau)\;\mathrm{d}t \tag{3.72}$$

where $E\,(t)\,\mathrm{d}t$ is the fraction of latex particles in the exit stream with age t. Because latex particles are very small and have a density close to that of water, the continuous phase, it is reasonable to assume that the residence-time distribution of latex particles and the aqueous phase are the same (latex particles follow streamlines).

It is further assumed that the role of molecularly dissolved emulsifier in the aqueous phase can be neglected relative to the amount of emulsifier in micelles and adsorbed on latex particles. Additional assumptions are that [S] $\gg$ CMC and that

$$a_\mathrm{s}\,[\mathrm{S}]\;N_\mathrm{A} = A_\mathrm{m} + A_\mathrm{p} \tag{3.73}$$

The number of particles is then given by

$$N_\mathrm{p} = \frac{R_{\mathrm{i,\,w}}\,\tau}{(1+A_\mathrm{p}/A_\mathrm{m})} \tag{3.74}$$

The particle surface area A_p for spherical latexparticles with various ages and sizes thus becomes

$$A_\mathrm{p} = 4.85\int_0^N v^{2/3}\,\mathrm{d}N_\mathrm{p} \tag{3.75}$$

Substitution of $v = f\,(K_\mathrm{p}, t, [\mathrm{M}]_\mathrm{p}, \bar{n})$ into Equation (3.75), where $[\mathrm{M}]_\mathrm{p}$ is constant (due to the very rapid diffusion of monomer from monomer droplets to polymer particles and, if monomer droplets are absent, due to rapid diffusion of monomer from polymer particle to polymer particle; the direction of monomer diffusion should be towards older and larger polymer particles) and $\bar{n} = 0.5$ and combination with Equations (3.72) and (3.74) then gives

$$N_\mathrm{p} = \frac{R_{\mathrm{i,w}}\,\tau}{\left[1+\frac{K_1 R_{i,\mathrm{w}}\,\tau}{a_\mathrm{s}\,[s]}\left(\frac{K_\mathrm{p}\,\tau\,[\mathrm{M}]_\mathrm{p}}{l-K_2\,[\mathrm{M}]_\mathrm{p}}\right)\right]} \tag{3.76}$$

As can be seen the comparison of Equations (3.74) and (3.76), the second term in the denominator of Equation (3.76) is analogous to the quantity $A_\mathrm{p}/A_\mathrm{m}$. At low concentrations of emulsifier [S] and high values of $R_{\mathrm{i,\,w}}$ and τ, it can be assumed that $A_\mathrm{p}/A_\mathrm{m} \gg 1$, so Equation (3.76) takes on the simplified form

$$N_\mathrm{p} = \frac{a_\mathrm{s}}{K_1}\,\frac{[\mathrm{S}]}{(K_\mathrm{p}\tau)^{2/3}}\left(\frac{1-K_2\,[\mathrm{M}]_\mathrm{p}}{[\mathrm{M}]_\mathrm{p}}\right)^{2/3} \tag{3.77}$$

Substitution into Equation (3.42) then gives

$$\mathrm{R_p} = K_3\,[\mathrm{M}]_\mathrm{p}\,\frac{a_\mathrm{s}\,[\mathrm{S}]\;K_\mathrm{p}^{1/3}}{\tau^{2/3}}\left(\frac{1-K_2\,[\mathrm{M}]_\mathrm{p}}{[\mathrm{M}]_\mathrm{p}}\right)^{2/3} \tag{3.78}$$

Here the constants K_1–K_3 are functions of the specific volumes V_m and V_p of monomer and polymer as well as of the molecular masses of the monomers; K_1 and K_3 contain in addition the assumed constant $\bar{n} = 0.5$ within the latex particles [771].

In order to compare exprimental data obtained over a wide range of conditions, it is convenient to rewrite Equation (3.76) in dimensionless form [772]:

$$\left(\frac{R_{\mathrm{i,\,w}}\,\tau}{N_\mathrm{p}}\right) = 1 + K_1\,\frac{R_{\mathrm{i,\,w}}\,\tau}{a_\mathrm{s}\,[\mathrm{S}]}\left(\frac{\tau K_\mathrm{p}\,[\mathrm{M}]_\mathrm{p}}{1-K_2\,[\mathrm{M}]_\mathrm{p}}\right)^{2/3} \tag{3.79}$$

or

$$\pi_1 = 1 + \pi_2$$

If N_p is expressed in terms of Equation (3.42) and introduced into Equation (3.79), what results is a second dimensionless equation for R_p:

$$\frac{R_{\mathrm{i,w}}\,\tau K_\mathrm{p}\,[\mathrm{M}]_\mathrm{p}\,\bar{n}}{R_\mathrm{p} N_\mathrm{A}} = 1 + K_1\,\frac{R_{\mathrm{i,w}}\,\tau}{a_\mathrm{s}\,[\mathrm{S}]}\left(\frac{\tau K_\mathrm{p}\,[\mathrm{M}]_\mathrm{p}}{1-K_2\,[\mathrm{M}]_\mathrm{p}}\right)^{2/3} \tag{3.80}$$

or

$$\pi_3 = 1 + \pi_2$$

Comparisons of data supplied by three different authors [771], [772], [776] are presented in

Figures 58 A and 58 B. In Figure 58 A, essentially all of the points lie above the 45° line; that is, fewer latex particles are formed than predicted by theory. By contrast, the experimental values for R_p in Figure 58 B, which are more precise, correspond well to the theoretical straight line. Overall, one may conclude that in the case of styrene the theory is well substantiated. The Gershberg – Longfield theory has been extended and modified a number of times. Thus DeGraff and Poehlein dropped the assumption that $\bar{n} = 0.5$ and instead calculated $\bar{n}$ using the Stockmayer – O'Toole solution for different particle sizes (Eq. 3.41) [772]. This accounts for the possibility of more than one radical per particle for the larger particles. Nomura et al. [773] also applied Equation (3.53), according to which radicals are absorbed more rapidly into latex particles than into micelles, to continuous emulsion polymerization and obtained a prediction that is in better agreement with experiment (as compared to that in Fig. 58 A). Brooks [794] discusses various equations for the entry of radicals into latex particles and micelles, assuming among other things that micelles disintegrate only slowly under subsaturation conditions, and that even in the presence of micelles the surface of the latex particle may not be saturated with emulsifier.

● calculated from values for R_p with the assumption that $\bar{n} = 1/2$

The existence of multiple steady states for the isothermal operation of a CSTR was first demonstrated in the case of continuous emulsion polymerization by Gerrens et al. [776–778], although it had earlier been predicted on theoretical grounds for autocatalytic processes in general [795–806]. Autocatalytic acceleration here is a consequence of the Trommsdorff –Norrish effect. The mass balance for monomer at steady state is given by

$$\dot{v}\,[\mathrm{M}]_0 - \dot{v}\,[\mathrm{M}] - R_p V = 0 \tag{3.81}$$

where $\dot{v}$ is the volumetric flow rate to and from the reactor, $[\mathrm{M}]_o$ is the monomer concentration in the feed, [M] is the monomer concentration in the reactor and exit stream, V is the volume of the reacting mass in the reactor, and R_p is the rate of polymerization in the reactor. Furthermore,

$$\frac{1}{\tau}\left([\mathrm{M}]_0 - [\mathrm{M}]\right) = R_p \tag{3.82}$$

where $\tau = V/\dot{v}$ is the mean residence time in the reactor.

Figure 59 shows a graphical solution of Equation (3.82) and R_p versus monomer concentration, in which data have been plotted as a function of both monomer concentration [M] and conversion X. At low values of mean residence time τ, there is one intersection (one solution) between experimental $R_p = f([\mathrm{M}])$ and the straight line (Eq. 3.82) which implies a single stable operating point at low conversion. By contrast, longer residence times lead to three points of intersection, with stable operating points at both low and high conversions and an unstable operating point at an intermediate conversion. For a train or cascade of n stirred reactors there may be as many as $n + n(n+1)/2$ stable operating points and n unstable operating points for the individual reactors as well as $n+1$ stable states for the entire cascade. Oscillations in the number of particles, the polymerization rate, and the interfacial tension have attracted considerable theoretical attention. These are attributed to bursts of particle formation that accompany swings between states of supersaturation of the latex particle surfaces, indicating large amounts of free emulsifier (and micelles), and states characterized by undersaturation, in which particle formation almost ceases. This phenomenon has long been recognized in industrial-scale continuous emulsion polymerization [733] and has now been thoroughly investigated in the case of styrene [771], [778], methyl methacrylate [786], [807], [808], and vinyl acetate [786], [798], [799], [809].

Figure 60. Oscillations in the continuous emulsion polymerization of vinyl acetate at three different initiator concentrations [I]. Comparison between experimental (○ · ○ · ○) [786] and calculated (– – –) values [787]

Model calculations are available for styrene [800], vinyl acetate [787], [790], [791], and vinyl chloride [785]. Figure 60 illustrates the close agreement between experiment and theory. Radical desorption has a strong influence (with accompanying more rapid polymer particle nucleation rates) on the oscillatory behavior of continuous emulsion polymerization in a CSTR [810–812] and radical desorption rate constants have been measured using a CSTR [810], [813]. In the absence of particle nucleation, oscillations (at least those not due to thermal effects) do not occur. A CSTR (with split flow) or tubular reactor operating as a polymer particle seed generator in series with one or more larger finishing reactors has been used to eliminate oscillations for Case 1 systems (vinyl acetate and vinyl chloride) [785], [646], [814], [815].

To complete the discussion of emulsion polymerization, a few brief comments will be made about an area which has almost been completely neglected in the literature. This is the effect of cross-linking in the polymer particle on emulsion polymerization kinetics and modeling (effect on particle nucleation and growth). The first and very important effect of cross-linking is on the equilibrium swelling of polymer particles by monomer. Taking into account the elastic free energy change due to the cross-linking network structure as well as the free energy contributions of mixing and interfacial tension, it is possible to derive an equation which gives the equilibrium monomer concentration in polymer particles

$$\frac{2V_1\sigma}{rRT} = -\left[\ln(1-\varphi_p) + \varphi_p + \chi\varphi_p^2\right] - \left(\varphi_p^{1/3} - \frac{\varphi_p}{2}\right)\left(\frac{\varrho_p}{\varrho_M}\right)\bar{\varrho}_{el} \tag{3.83}$$

where ϱ_{el} is the elastic cross-link density of the accumulated polymer [816]. The first thing to notice is that cross-linking reduces the monomer concentration and hence the volumetric growth rate of polymer particles. According to Equation (3.47) or (3.49) the number of polymer particles nucleated in Stage I will be larger. In an experimental study using styrene and divinyl monomers, NOMURA et al. have confirmed [817] that much higher numbers of particles are generated when initiated particles are cross-linked. An obvious effect of cross-linking is the strengthening of the Trommsdorff – Norrish effect with concomitant earlier and larger decrease with conversion of the termination constant and the consequences thereof. When the molecular mass of primary chains produced in smaller polymer particles is larger, one might expect gelation to occur earlier in smaller particles. There are clearly many interesting phenomena related to cross-linking in latex particles which await investigation.

3.3.4. Miscellaneous Processes

The modeling of high-pressure tubular and autoclave reactors for the manufacture of LDPE

has received a great deal of attention [818–836]. These models are notable for the detailed kinetics, which include transfer to polymer, backbiting, and β-scission in an attempt to calculate both short- and long-chain branching frequencies. The polymerizations are almost adiabatic, with large temperature increases, and phase separation between ethylene and polyethylene may occur in autoclave reactors. The tubular reactor is considered to be in plug flow, while mixing in the autoclave is rather complex and various mixing models have been considered. A comprehensive copolymerization model for ethylene and comonomers in a high-pressure continuous tubular reactor has been developed [836].

A comprehensive tubular reactor model for the solution polymerization of vinyl acetate has been developed by Hamer and Ray [837]. The kinetics employed account for transfer to polymer and reaction with terminal double bonds (trifunctional branching frequencies are calculated). The model solves the equations of motion for both axial and radial velocity profiles. Experimental validation of the model has been carried out.

The bulk and solution polymerization of styrene in tubular reactors has also been extensively studied both theoretically and experimentally [375], [838]. Spatial distributions of velocity, temperature, and concentration were modeled [838] and it was shown that for tube diameters > 2 cm, thermal runaway may occur. Internal mixers were used in larger diameter tubes to give better radial mixing and this technique appears to give polystyrenes with high molecular mass at a productivity of commercial interest [375]. References to other important studies on styrene production in tubular reactors may be found elsewhere [375], [838].

Chemical Modification of Polymers in Extruders The commercial incentive for the chemical modification of polymers by chain scission, long-chain branching, cross-linking, and grafting is the enhancement of the physical and chemical properties of polymers and polymer mixtures (alloys, blends, additives) and/or improvement of their processability. In many cases, the extruder has been found to be an effective chemical reactor in which chemical modification of high molecular mass polymers in the melt can be done economically for low-volume products. It is particularly effective for chemical modification of high molecular mass, solvent-free, commodity polymers to tailor-made products to meet the growing diversity in polymer applications. The extruder reactor provides short and controlled residence times; efficient mixing, particularly for reactants at low concentrations; and good heat transfer. Multistage reaction, with sequential feeding of reactants and removal of byproducts, is possible. There are certain advantages of twin-screw over single-screw extruders [839]. These include: intense shear mixing (with better surface renewal rates) giving molecular-level mixing (micromixing), improved heat transfer, multistage feeding, venting of volatile byproducts, and screw speed can be changed without changing the throughput. These attributes of the twin-screw extruders are ideal for chemical modification where a small amount of the low molecular mass compound to be grafted on the polymer chains must be homogeneously mixed with a highly viscous base polymer.

Chemical modifications are often carried out using free-radical reactions in the temperature range 170 °C – 350 °C. When a polymer containing a peroxide and a compound to be grafted is melt processed, chain scission, long-chain branching, cross-linking, and grafting reactions may occur simultaneously. To optimize product properties, the rates of these reactions must be controlled.

Chain Scission. Polymer chain scission occurs when chemical bonds (usually C – C) along the backbone break. Since a higher molecular mass chain has a greater number of such bonds, it experiences chain scission preferentially (for polypropylene, scission seems to be random with respect to the position of the bond along the chain backbone [840], [841]). Therefore, the broad MWDs, usually found for polyolefins narrow as the average molecular mass falls. With random scission occurring exclusively, the limiting polydispersity for all initial MWDs is two and the limiting MWD is Flory's most-probable distribution. A reduction in molecular mass improves processability. The outstanding commercial example of the use of controlled chain scission of polypropylene (PP) is in the production of controlled-rheology PP used for fiber manufacture, film-extrusion, and for fast molding applications [842].

Long-Chain Branching and Cross-Linking. Long-chain branches (tetrafunctional) are formed when radical centers on the backbone of polymer chains experience bimolecular termination by combination. If this long-chain branching process continues, a three-dimensional network (cross-linked gel) is formed. The production of higher molecular mass chains by long-chain branching produces a polymer that exhibits increased die swell and melt strength, and improved strain-hardening properties [842].

Cross-linking of polymer chains results when bimolecular coupling (via bimolecular termination by combination of polymer backbone radicals or the reaction of grafted chemical groups such as those with silane functionality [843], [844]) of polymer chains to form tetrafunctional branches occurs repeatedly. The cross-linked polymer is a mixture of polymeric gel, of effectively infinite molecular mass, and sol which is made up of linear and branched chains. Property enhancement due to cross-linking includes: increased service temperature, solvent resistance, flexural modulus, low-temperature impact strength, environmental stress cracking resistance, and reduced creep [842].

Grafting onto polymer chains can occur when a mixture of the polymer, peroxide, and unsaturated or saturated compound to be grafted are melt processed in an extruder. For example, acrylic acid or maleic anhydride can be grafted onto PP or PE to enhance compatability with more polar blends or to improve adhesion to metals, glass fibers, and to other polymer types [845], [846]. Vinyl silanes can be grafted to polyolefins to subsequently produce cross-links in the presence of moisture [843]. Functionalized additives (antioxidants, flame retardants, pigments) can be grafted onto the host polymer to give the desired property enhancement. These chemically bound additives are effectively mixed on a molecular scale and do not diffuse out of the matrix during use [847].

Source of Radicals. During normal extrusion of polyolefins, alkyl radicals may be formed thermomechanically, but at too low a rate to initiate chemical modification to the extent normally desired. To provide a suitable source of radicals, organic peroxides are added to the polymer before melt processing. In these applications the peroxides used must generate radicals which are sufficiently energetic to abstract backbone atoms and generate backbone radical centers.

Other reaction types, including anionic, cationic, anionic coordination, and condensation can be carried out in an extruder reactor [839]. Kowalski [848] describes an extruder process for halogenation of butyl rubber. Saleem and Baker [849] describe a process in which polystyrene and polyethylene along with their reactive counterparts (polystyrene with oxazoline groups, and polyethylene with carboxylic acid groups) are reacted to form polymeric compatabilizers in situ.

Kinetics and Extruder Reactor Modeling. Reviews of the kinetics of chemical modification of polymer by free-radical mechanisms are available [839], [850], [851]. Motha et al. [852] have developed a model for the grafting of unsaturated acids and silanes on polyethylene. This model does not attempt to predict the gelation point nor the gel/sol ratio in the post-gel region. A very general model which permits one to follow the change in the MWD of polymer being modified by simultaneous random scission, long-chain branching, cross-linking, and grafting has been developed [850], [851]. The model, which is in the form of an integro-differential equation is based on a simpler version developed earlier by Saito [851], [852]. Saito found an analytical solution for the limiting case of random scission occurring exclusively. Kimura [853] obtained a limiting analytical solution for the case in which random cross-linking is occurring exclusively. The general case can be handled by using the method of moments to give the molecular mass averages. The widely used Charlesby – Pinner equation was obtained by using an idealization which is questionable [854]. Simultaneous scission and cross-linking are treated as two processes in series, with random scission occurring first and then cross-linking. In addition, the initial MWD must be Flory's most probable distribution. Numerical methods must be used to solve the integro-differential equation for the case of simultaneous scission and cross-linking. This is not a trivial problem and has not been successfully solved to date.

The design of extruders for reactive processing is much more challenging than for purely physical processing [839]. Extruders must handle polymer melts with continuously changing

properties. Residence-time distribution (RTD) and micromixing can significantly affect the properties of the chemically modified polymer. One of the important advantages of twin-screw over single-screw extruders is the greater control they allow over RTD and mixing. The modeling of conventional or physical extrusion processes has been well documented in the literature, particularly for single-screw extruders. Details of the modeling of extruders may be found in the review article by TZOGANAKIS [839]. TZOGANAKIS et al. [855] developed a comprehensive rheokinetic model for the random scission of isotactic polypropylene in a single-screw extruder. Finite-element or finite-difference methods will play an important role in the solution of the three-dimensional flow equations for both single and twin-screw extruders [856].

3.3.5. Ionic Polymerization Modeling

3.3.5.1. Introduction

The most powerful processes for the control of MWD of linear chains are living anionic and cationic polymerizations. These processes are interesting from the point of view of process engineering because the MWD of the product can be varied widely by changing the RTD of the process or by oscillating the process in a controlled manner. These living ionic processes will be considered from this perspective in Section 3.3.6.1.

3.3.5.2. Heterogeneous Coordination Polymerization

The commercially important anionic coordination processes (heterogeneous ZN polymerization) are now discussed. SEPPALA and AUER have published an excellent review of much of the relevant subject matter [857]. Third- and fourth-generation catalysts have already been commercialized for slurry polymerizations. These newer catalysts possess high and stable activity, high stereospecificity independent of polymerization time, and increase in activity with increasing temperature up to about 80 °C. Electron donors may be used to regulate isotacticity. Catalysts may also be designed to control the size and shape of polymer particles.

The gas-phase UNIPOL process has become one of the most successful commercial processes for the production of polyolefins [858]. In this process, homo- and copolymerizations of ethylene with α-olefin comonomers are carried out in a fluidized-bed reactor using heterogeneous Ziegler – Natta or Philips supported metal oxide catalysts [859].

Modeling of these processes can be classified into three categories [857], [860]:

1) Microscale kinetic phenomena: coordination kinetic mechanism, multiple active site types, stereoregularity, copolymer composition and molecular mass distributions, and catalyst deactivation kinetics
2) Mesoscale particle phenomena: fracture of catalyst particles, heat generation in particles, mass transfer, and growth and influence of changing properties of reaction environment
3) Macroscale reactor phenomena: overall mass and energy balances, gas – liquid mass transfer effects, influence of reaction medium, effects of particle motion, and heat transfer limitations and influence of reactor type

Similar modeling categories could be considered for the manufacture of PVC and EPS by free-radical suspension polymerization, where particle morphology and foamed cell structure are important considerations.

One of the major challenges in modeling heterogeneous coordination polymerizations has been to rationalize the very broad MWDs and copolymer composition distributions (CCD) that are often observed. There have been two schools of thought. RAY and coworkers have until recently attempted to explain the broad MWDs in terms of diffusional resistances for reactants, which increase as the catalyst particles are enveloped by a growing shell of polymer. An additional resistance may result from the crystallization of polymer chains. Others have attempted to explain the broad MWDs and CCDs as due to multiple sites of different activity. These sites have different compositions. To model a binary copolymerization it can be assumed that each site type produces a polymer with STOCKMAYER's bivariate distribution [861], [862]. The more difficult problem is, of

course, to determine the number of active site types and the concentration of each. Two active-site-type models have been used [862], [863] as well as site-type distribution functions [864]. Among the diffusion-limited models, the multigrain model is the most comprehensive. It is assumed that fragmentation of the original catalyst particle is complete before appreciable polymer has been produced [865], [866]. Thus, the large macroparticle is composed of many catalyst fragments encapsulated by polymer [865], [867–869]. Both macroparticle and microparticle mass transfer can be important for large catalyst particles of high activity [857]. Ray et al. [868] found that the maximum possible temperature rise in both micro and macroparticles is negligible in slurry polymerization of propylene. However, in gas-phase processes the temperature inside the polymer particle could reach its melting point under some conditions [866]. Near the beginning of polymerization, the polymer particles may heat up because of the high catalyst activity and polymerization rate. In summary, it can be said that the very broad MWDs and CCDs can be explained by invoking multiple site types. However, under certain conditions, mass- and heat-transfer resistances may also play a significant role. The development of more realistic models for copolymerization on heterogeneous coordination catalysts will require the measurement of the bivariate distribution of molecular mass and composition by a combination of analytical techniques such as TREF/GPC and TREF/NMR to observe the detailed microstructure of the copolymer chains [870].

3.3.6. Process Variables, Reactor Dynamics/ Stability, On-Line Monitoring and Control

3.3.6.1. Influence of Reactor Type and Configuration on Molecular Mass and Copolymer Composition Distributions, and on Long-Chain Branching and Cross-Linking

Survey of Idealized Reactor Types and Simple Polymerization Reactions. Molecular mass and copolymer composition distributions, long-chain branching, and cross-linking can exert a significant influence on the properties of all polymers. It is thus important to know the distribution functions that correspond to various polymerization mechanisms and how these distributions change with reactor type and configuration. Another way of expressing this is to note that these molecular properties are strong functions of the residence-time distribution of the polymerizing mass and that once an optimal residence-time distribution has been established, one can choose reactor types and manipulate reactor configuration to obtain this residence-time distribution in a practical manner. Most deviations of predicted and measured molecular properties are likely to be due to assumptions about levels of micromixing and segregated flow and the comparison of predicted instantaneous molecular properties with measurements of these properties on accumulated polymer (e.g., instantaneous properties can change with time in a batch reactor as, say, [M] decreases and hence the distributions for molecular properties for the accumulated polymer will have larger variances). From an industrial standpoint, however, any process of interest involves high – if not complete – conversion, and a wide variety of batch and continuous reactors is utilized. The relationships between reactor types and configurations and the various polymerization mechanisms are often quite complex, and it will only be possible within the confines of this article to treat certain simple ideal reactors and reaction types.

Figure 61 shows four ideal reactors, characterizing them on the basis of residence-time distribution and the temporal and spatial course of chemical reaction. Batch reactors (BR), continuous plug flow reactors (CPFR), and homogeneous continuous stirred-tank reactors (HCSTR) are treated in the article Stirred –Tank and Loop Reactors. With a homogeneous continuous stirred-tank reactor, perfect mixing down to the molecular level is assumed, and for a CSTR with an ideal residence-time distribution, there are by definition no spatial variations in temperature and concentrations. Mixing at the molecular level is often called "micromixing". This condition is often not achieved in practice, however, and for this reason a fourth ideal reactor type is introduced, the segregated continuous stirred-tank reactor (SCSTR) [801–803]. Here the fluid phase is regarded as subdivided into many small

isolated compartments. Each compartment contains a large number of molecules, which are permanently confined within the limits of that compartment; therefore, the individual compartments function as miniature batch reactors with different residence times in the flow reactor. The compartments themselves are taken to be ideally mixed, leading to what is called "macromixing" despite total segregation of molecules in different compartments. Thus, the sum of all the compartments in a segregated continuous stirred-tank reactor have the same residence-time distibution as the contents of the homogeneous stirred-tank reactor. A macroscopic mean taken over all the compartments in the effluent stream and in the reactor itself would show concentrations and temperature that are constant both spatially and with respect to time. On the other hand, a probe capable of microscopic sampling of individual compartments would reveal concentrations that varied in a statistical manner from one compartment to another. Given the high viscosity of a typical polymerizing solution it is quite likely that many solution polymerizations actually occur in segregated systems [804]. Ideal reactors are discussed in greater detail in, for example, [795], [805].

Polymerization reactions can be divided according to their kinetics into three classes:

1) Monomer coupling with bimolecular termination (e.g., free-radical polymerization)

$$\left.\begin{array}{l} \mathrm{I} \xrightarrow{K_d} 2\,\mathrm{R}^{\bullet}_{in} \\ \mathrm{R}^{\bullet}_{in} + \mathrm{M} \xrightarrow{K_i} \mathrm{R}^{\bullet}_{1} \end{array}\right\} \text{initiation}$$

$$\mathrm{R}^{\bullet}_{r} + \mathrm{M} \xrightarrow{K_p} \mathrm{R}^{\bullet}_{r+1} \qquad \text{propagation}$$

$$\mathrm{R}^{\bullet}_{r} + \mathrm{R}^{\bullet}_{s} \left.\begin{array}{l} \xrightarrow{K_{td}} \mathrm{P}_r + \mathrm{P}_s \\ \quad\text{by disproportionation} \\ \xrightarrow{K_{tc}} \mathrm{P}_{r+s} \\ \quad\text{by combination} \end{array}\right\} \begin{array}{l}\text{bimolecular}\\ \text{termination}\end{array}$$

2) Monomer coupling without termination (e.g., living anionic polymerization)

$$\mathrm{I} + \mathrm{M} \xrightarrow{K_i} \mathrm{P}^{*}_{1} \qquad \text{initiation}$$

$$\mathrm{P}^{*}_{r} + \mathrm{M} \xrightarrow{K_p} \mathrm{P}^{*}_{r+1} \qquad \text{propagation}$$

3) Polymer coupling (e.g., polycondensation)

$$P_r + P_s \xrightarrow{K} P_{r+s} \qquad \text{propagation}$$

In both cases of monomer coupling, many individual monomer molecules add successively to the growing chains. Monomer coupling with bimolecular termination is characteristic of free-radical polymerizations. Termination may occur through the combination of two growing radicals (degree of coupling $K = 2$). Termination by disproportionation is an example of a process in which $K = 1$ [806]. Monomer coupling without termination is encountered, for example, in living anionic or cationic polymerizations. Polymer coupling between macromolecules is characteristic of polycondensation and polyaddition reactions. The discussion that follows has been restricted deliberately to the simplest reactions possible, with precisely simultaneous initiation of all active centers in the case of anionic polymerization and exact stoichiometric balances in polycondensation. Chain-transfer reactions will be neglected, as will exchange reactions (e.g., transesterification, transamidation). A few consequences of these complex reactions are outlined in [871].

The three types of polymerization differ considerably in the way the degree of polymerization of the accumulated polymer $\bar{P}_N$ (averaged over the course of the conversion process) changes as a function of conversion. As shown in Figure 62, a high degree of polymerization $\bar{P}_N$ is reached at very small conversions in free-radical polymerization. In a batch reactor this value subsequently decreases with increasing conversion as a consequence of decrease in the monomer concentration [M] (assuming that the Trommsdorff effect is negligible and that the radical initiation rate is essentially constant). With living polymerization in the absence of termination reactions, on the other hand, $\bar{P}_N$ increases linearly with conversion, and in polycondensation a high degree of polymerization is achieved only at very high conversion (e.g., 95 % conversion is required to reach $\bar{P}_N = 20$).

Figure 61. Schematic illustration of the course of reaction in various types of reactors
E/E_0 = mass fraction of the material throughput traversing the reactor with a residence time between t and $t + dt$; C_A = concentration of component A; t = time; τ = mean residence time; x = spatial coordinate; L = reactor length; n = order of the reaction

Figure 62. Cumulative degree of polymerization $\bar{P}_N$ as a function of conversion for various polymerization reactions a) Monomer coupling with termination; b) Monomer coupling without termination; c) Polymer coupling

Batch and plug flow reactors provide equivalent results, so they can conveniently be considered together. There are thus nine different combinations possible for the three types of polymerization and the three ideal reactor types, as summarized in Table 5, which also includes a qualitative description of the resulting molecular mass distributions.

3.3.6.1.1. Monomer Coupling with Bimolecular Termination Plug Flow and Batch Reactors (CPFR/BR)

Under the assumption that R_1 = constant (constant radical generation rate; half-life $t_{1/2}$ of the initiator $\gg$ residence time τ of reactor contents) and [M] = constant (small conversion increment), the instantaneous degree of polymer-

Table 5. Molecular mass distribution for polymerization reactions in various types of reactors

Reaction	Reactor		
	Continuous plug flow (CPFR) or batch (BR) reactor	Homogeneous continuous stirred-tank reactor (HC-STR)	Segregated continuous stirred-tank reactor (SCSTR)
1. Monomer coupling with termination (e.g., radical polymerization)	1.1. distribution increasingly broader than Schulz–Flory distribution with increasing conversion	1.2. Schulz–Flory distribution PDI = 2 for $k = 1$ PDI = 1.5 for $k = 2$	1.3. increasingly broader distribution than 1.1 with increasing conversion
2. Monomer coupling without termination (e.g., anionic living polymerization)	2.1. Poisson distribution for $K_I \geq K_p$ Gold distribution for $K_I < K_p$	2.2. Schulz–Flory distribution	2.3. Schulz–Flory distributon for $x = 0$ Poisson distribution for $x = 1.0$
3. Polymer coupling (e.g., polycondensation)	3.1. Schulz–Flory distribution	3.2. much broader than the Schulz–Flory distribution	3.3. between 3.1 and 3.2

ization P_N, when termination is exclusively by disproportionation, is given by

$$P_N = \frac{K_p\,[M]}{(K_{td} R_I)^{1/2}} = \frac{1}{(1-\varphi)} \tag{3.84}$$

and the instantaneous mass chain length distribution is given by the Schulz–Flory (or most probable) distribution [872], [873]:

$$W(r) = (1-\varphi)^2\, r\varphi^{r-1}$$
$$\approx (1-\varphi)^2\, r \exp = [-(1-\varphi)\, r] \tag{3.85}$$

where

$$\varphi = \frac{k_p\,[M]}{k_p\,[M] + (K_{td}\, R_I)^{1/2}}$$

The breadth of the distribution is described either by the nonuniformity U or by the polydispersity index PDI.

$$U = \frac{P_W}{P_N} - 1 \tag{3.86}$$

$$\overline{\mathrm{PDI}} = \frac{P_W}{P_N} = \frac{Q_2 Q_0}{Q_1^2} \tag{3.87}$$

with PDI = 2 for $k = 1$ (bimolecular termination by disproportionation); PDI = 1.5 for $k = 2$ (bimolecular termination by combination). The PDI (or U) can be expressed in terms of the moments of the frequency distribution of chain lengths Q as shown in Equation (3.87). Thus, if one examines the entire range of conversions (i.e., dropping the assumption that [M] = constant) what results with increasing conversion x (decreasing monomer concentration [M]) is a set of Schulz–Flory distributions with different P_N for decreasing degrees of polymerization, as shown in Figure 63.

Figure 63. Mass distribution $W(r)$ of instantaneously formed polymer for monomer coupling with termination. Batch reactor at small conversion increments, or homogeneous continuous stirred-tank reactor.
$P_{N,0} = 1000$, $P_{N,x} = P_{N,0}(1-x)$; degree of coupling $k = 1$

Note that PDI = 2 for all the molecular mass distributions (actually mass chain length distributions to be more precise) in Figure 63. By contrast, the statistical variance σ^2 of the associated

frequency distribution decreases with increasing conversion. However, since $\sigma^2 = P_N^2$ (PDI − 1), σ^2 continuously decreases as P_N decreases with conversion, except in the case of a monodisperse MWD with PDI = 1. For this reason, one of the quantities PDI or U is preferred for expressing distribution breadth.

Figure 64. Cumulative mass distribution $W(r)$ for polymer formed throughout the conversion interval $x = 0$ to $x = x$ for monomer coupling with termination in a BR/CPFR $\bar{P}_{N,x} = 1000$, $k = 1$

Integration of the distributions in Figure 63 with appropriate weighting factors gives the molecular mass distribution of the final polymer product at the end of the batch [874–877]. To simplify comparison, the distributions in Figure 64 have been calculated in such a way that for each conversion x, the degree of polymerization of the accumulated polymer $\bar{P}_N = 1000$. It is clear that distributions broaden with increasing conversion. Representations of PDI and $\bar{P}_N$ as functions of conversion follow in Figures 68 and 69. Theoretical treatments of this case can be found in [878–888] and in Section 2.2. Before leaving CPFR/BR reactors, the following points should be noted. Firstly, the Trommsdorff effect can have a significant effect on molecular mass development with increasing conversion. The significant lowering of either K_{tc} or K_{td} when chain transfer to small molecules (monomer or chain-transfer agents) is negligible can cause dramatic increases of molecular mass with conversion. See, for example, data for the change of molecular mass distribution with conversion for the bulk homogeneous polymerization of methyl methacrylate [380]. On the other hand, when chain transfer to monomer (as in vinyl chloride polymerization) or to chain-transfer agent produces most of the polymer chains, the Trommsdorff effect has no influence on molecular mass development. In particular, when chain transfer to monomer produces most of the polymer chains, molecular mass development will depend on temperature and be independent of process type and reactor type [889].

Figure 65. Radical polymerization of styrene in an HCSTR at low viscosity. Comparison between observed (– – –) and calculated (—-) molecular mass distributions [891]
Reaction conditions:
Feed: 2.39 mol/L monomer, 7.44 mol/L solvent (benzene), 0.0152 mol/L initiator (AIBN); temperature 74.1 °C; viscosity $\eta = 1.5$ mPa · s; mean residence time $\tau = 160$ min

Figure 66. Mass distribution $W(r)$ of polymer formed by monomer coupling with termination in an SCSTR [883] $P_{N,0} = 2000$; $k = 2$

In a CPFR/BR, the width of the copolymer composition distribution can be substantial if one monomer type reacts much faster than the other in propagation. For the same final conversion, the residence-time distribution for CPFR/BR is ideal compared to the other reactor types when minimization of long-chain branching, cross-linking and gel/sol ratios is required.

Figure 67. Mass distribution for radical polymerization in three different reactors [885]
Conversion $x = 0.6$; $P_{N,0} = 1000$; $k = 2$

Figure 68. Polydispersity index PDI = P_W/P_N as a function of conversion for radical polymerization in three different reactors

Homogeneous Continuous Stirred-Tank Reactor (HCSTR). DENBIGH has shown that in a homogeneous CSTR two opposing factors influence the molecular mass distribution [878–881]. The constancy of [M] at steady state leads to a narrowing of the distribution relative to that obtained in a batch reactor, while the range of residence times leads in principle to broadening of the distribution. However, in radical polymerization, the lifetime of a growing radical is ca. 1 s, very small compared to the mean residence time of any industrial reactor. This first factor (constant [M]) thus predominates and the resulting distribution is narrower in an HCSTR than in a CPFR/BR. With polymerization reactions that do not involve termination, the lifetime of the growing chain is comparable to the mean residence time of the reactor, so that broadening of the MWD by the residence-time distribution is dominant.

In the steady state with [M] = constant, the same conditions are present in the stationary state as in a batch reactor at low conversion or at some higher conversion over a small conversion increment, resulting in the Schulz – Flory distribution described by Equations (3.85) – (3.87). A comparison of observed and calculated molecular mass distributions for an HCSTR, as shown in Figure 65, indicates very good agreement in regions of low viscosity where the Trommsdorff – Norrish effect plays no significant role. Even when the Trommsdorff – Norrish effect is appreciable, the Flory – Schulz distribution should still apply when diffusion-controlled bimolecular termination is not chain-length dependent [358]. Additional experimental studies on continuous free-radical polymerization are described in [367], [373], [890–895].

Experimental	Theoretical
$\bar{M}_W = 20\,990$	$M_W = 20\,440$
$\bar{M}_N = 14\,020$	$M_N = 13\,650$
PDI = 1.50	PDI = 1.50

Segregated Continuous Stirred-Tank Reactor (SCSTR). Individual compartments, all of which can be regarded as miniature batch reactors, display residence times or reaction times according to the exit-age distribution function of a CSTR which is

$$E(t) = \frac{1}{\tau}\exp(-t/\tau) \tag{3.88}$$

The effect of segregation is a broadening of the MWD to a breadth greater than that for a batch reactor, and the breadth increases with conversion. Figure 66 provides several examples, starting with the Schulz – Flory distribution at a conversion $x = 0$. Figure 67 compares molecular mass distributions for free-radical polymerization in the three reactor types. The corresponding changes in the polydispersity index PDI are illustrated in Figure 68, and Figure 69 shows the degree of polymerization for the accumulated polymer as a function of conversion. Thus, the narrowest possible molecular mass distribution for free-radical polymerization is the Schulz – Flory distribution and it is obtained in an HC-STR, and the broadest distribution is obtained in a SCSTR. For additional theoretical studies, see [883], [885], [896], [897].

Figure 69. The course of the degrees of polymerization of the accumulated polymer $\bar{P}_N$ and $\bar{P}_W$ as a function of conversion during radical polymerization

3.3.6.1.2. Monomer Coupling Without Termination Plug Flow and Batch Reactors (CPFR/BR)

In the absence of termination reactions the kinetic chain length η corresponds to the ratio of the initial concentrations of monomer and initiator

$$\eta = \frac{[M]_0}{[I]_0} \tag{3.89}$$

or at incomplete conversion

$$\eta = \frac{[M]_0 - [M]}{[I]_0} = \frac{[M]_0\, x}{[I]_0} \tag{3.90}$$

If initiator molecules are counted as chain units

$$P_N = 1 + \eta \tag{3.91}$$

The assumption is made here that initiation is much faster than propagation, i.e., $K_i \gg K_p$. At $t = 0$, all active molecules will have a degree of polymerization $P_N = 1$, and the number of propagation steps per active site (i.e., the kinetic chain length) is $\eta = P_N - 1$. The case $K_i < K_p$ leads to a broader distribution [898], [899], but one that is still narrower than the Schulz – Flory distribution. The molecular mass distribution corresponds to a Poisson distribution [435, pp. 346 – 339], [900] (see also Section 2.2.2.2):

$$W(r) = \frac{e^{-\eta}\,\eta^{r-1}}{(1+\eta)\,(r-1)\,!} \tag{3.92}$$

with a polydispersity

$$\mathrm{PDI} = P_W/P_N = 1 + \frac{1}{\eta} \tag{3.93}$$

Figure 70. Mass distribution $W(r)$ of polymer formed by monomer coupling without termination in a SCSTR [885] $P_N = 100$; Schulz – Flory distribution for $x = 0$; Poisson distribution for $x = 1$

Thus the distribution becomes narrower as the contribution from statistical broadening decreases with chain growth (increase in η) (cf. the bottom curve in Fig. 71). A comparison of Equations (3.87) and (3.93), or inspection of Figure 70 indicates that Poisson distribution is significantly narrower than the Schulz – Flory distribution.

Figure 71. Polydispersity index PDI = P_W/P_N as a function of P_N for polymerization by monomer coupling without termination in a SCSTR [885]

Homogeneous Continuous Stirred-Tank Reactor (HCSTR). If it is assumed that chain growth terminates abruptly as growing chains leave the reactor, then the lifetime of an active growing chain is equal to its residence time in the reactor. According to [879–881], the molecular mass distribution in an HCSTR should be broader than for a CPFR/BR. Several authors have demonstrated that the Schulz – Flory distribution is obtained for living polymerization (with instantaneous initiation) in an HCSTR [882], [883], [885], [901–904].

Segregated Continuous Stirred-Tank Reactor (SCSTR). The rate of living polymerization is first-order with respect to [M], so R_p and x are the same for both HCSTR and SCSTR [795, pp. 309 – 331], [805]. Segregation inhibits total molecular mixing, whereas in an HCSTR all molecules are distributed according to Equation (3.88), this is true for a SCSTR only with respect to all compartments, each of which contains a large number of molecules with equal residence times. The molecular mass distribution is therefore subject to less broadening relative to a batch reactor than in the case of the HCSTR. At very low conversion, it is possible to assume constant monomer concentration, so the distributions in the three reactor types are almost identical. At high conversion the effect of the residence-time distribution diminishes. At complete conversion the lifetime of the active species must be significantly shorter than the mean residence time, and the molecular mass distribution becomes equivalent to that in a batch reactor. Figure 70 shows the transition from a Schulz – Flory to a Poisson distribution with increasing conversion. Figure 71 is a plot of polydispersity PDI as a function of P_N and x. The bottom curve (for $x = 1.0$) corresponds to Equation (3.93) for a batch reactor.

3.3.6.1.3. Polymer Coupling

Only the formation of linear chains, either from monomer of type A – B or from exact stoichiometric mixtures of monomer types A – A and B – B is considered here. Ring formation is also excluded.

Plug Flow and Batch Reactors (CPFR/BR). The functional group conversion p is defined as the fraction of functional groups that have reacted at a given time

$$p = \frac{N_0 - N}{N_0} \tag{3.94}$$

For the degree of polymerization it follows that

$$P_N = \frac{N_0}{N} = \frac{1}{(1-p)} \tag{3.95}$$

$$P_W = \frac{1+p}{1-p} \tag{3.96}$$

The molecular mass distribution is given by

$$W(r) = (1-p)^2\, r p^{r-1} \tag{3.97}$$

with

$$\mathrm{PDI} = P_W/P_N = 1+p \tag{3.98}$$

and is once again the Schulz – Flory distribution with PDI = 2 at high conversions [435,

pp. 336 – 339], [873], [882], [883], [902], [905–908].

Figure 72. Molecular mass distribution $W(r)$ of polymer formed by polymer coupling in a CPFR/BR [873]

	p	P_N	P_W	PDI
a) BR	0.998	500	999	1.998
b) SCSTR	0.9887	88.41	1000	11.31
c) HCSTR	0.9561	22.8	995	43.6

Figure 73. Molecular mass distribution $W(r)$ for polymerization by polymer coupling in three different reactors [883]

Figure 72 shows the molecular mass distribution at various conversions. For free-radical polymerization the Schulz – Flory distribution always has a PDI = 2 because φ, the probability of propagation, is almost always very close to unity. This is not so for polycondensations, where p can vary from 0 to 1, and thus PDI varies from 1 to 2.

Figure 74. Polydispersity index PDI = P_W/P_N as a function of P_N for polymer coupling [885]

Homogeneous Continuous Stirred-Tank Reactor (HCSTR). Monomer and polymer molecules are capable of reacting with each other throughout their entire residence time in the reactor. Thus, according to the principle of Denbigh [879–881], a broader molecular mass distribution is to be expected in an HCSTR than in a batch reactor. The broad distribution of residence times means that material leaving the reactor always contains a relatively large amount of monomer and polymer with a low degree of polymerization. On the other hand, with increasing molecular mass the probability of the formation of very large macromolecules by the coupling of two smaller ones increases greatly. Calculations give a very broad distribution (Fig. 73) in which the number-average degree of polymerization P_N is the same as in a batch reactor, but the weight-average P_W is much higher [883], [885], [902], [907], [909], [910]:

Figure 75. Composition of the copolymer produced in a batch reactor (BR) as a function of monomer composition of the charge as well as conversion
First column: instantaneous composition; second column: instantaneous compositions, starting with monomer ratios $[M_1]:[M_2] = 1:3$, $1:1$, and $3:1$; third column: cumulative compositions based on the same starting ratios

$$P_N = \frac{1}{1-p}$$

$$P_W = \frac{1+p^2}{(1-p)^2} \tag{3.99}$$

This corresponds also to a considerably higher PDI, which increases rapidly with increasing conversion (Fig. 74):

$$\mathrm{PDI} = \frac{1+p^2}{(1-p)} \tag{3.100}$$

Segregated Continuous Stirred-Tank Reactor (SCSTR). Segregation reduces the amount of polymer with very high or very low molecular mass [883], [885]. Figure 73 compares the molecular mass distributions expected for the three reactor types and Figure 74 shows the polydispersity index PDI as a function of P_N. In terms of both P_N and PDI, the SCSTR lies between the CPFR/BR and the HCSTR.

Note that the conclusions drawn in the preceding two sections are a result of purely theoretical considerations, and they actually have little to do with practice. On the one hand, Equation (3.95) (see also Fig. 62) indicates that attaining a reasonably high degree of polymerization requires a very high conversion; HC-

Figure 76. Ternary copolymerization in the system styrene (M_1), 2,5-dichlorostyrene (M_2), and acrylonitrile (M_3) [912]
A) Instantaneous copolymer composition (arrow point) as a function of composition of the monomer mixture (origin of the arrow); B) Partial azeotropes, where arrows outside the diagram indicate the positions of binary azeotropes

STR and SCSTR systems would therefore appear inappropriate (extreme viscosities would be inappropriate for a CSTR). On the other hand, many polycondensations and polyadditions are accompanied by rearrangements at the heteroatoms, including transesterifications or transamidations. This means that polymer with a Schulz – Flory distribution would be obtained even in an HCSTR [435, pp. 336 – 339], [911].

3.3.6.1.4. Copolymerization

The theory of copolymerization kinetics is covered in Section 2.3. However, the performance of the three reactor types (CPFR/BR, HCSTR, and SCSTR) were not compared and therefore this topic is considered here.

Copolymerization in CPFR/BR Reactors. Figure 75 gives several illustrations of compositional drift for binary copolymerization for various comonomer pairs in continuous plug flow and batch reactors. The first two columns are for the mole fraction of monomer 1 chemically bound in copolymer chains produced instantaneously (over a small conversion or time interval) as a function of mole fraction of free monomer 1 and of conversion. The third column shows the mole fraction of monomer 1 in the accumulated copolymer chains versus conversion. Azeotropes also occur in systems with more than two comonomers. Figure 76 shows a three-fold combination represented in terms of triangular coordinates. The compositions of various comonomer mixtures are indicated by the origins of arrows, with the corresponding arrow points showing the instantaneous compositions of the resulting polymers. The length of an arrow is thus a measure of the deviation between compositions of free monomer and copolymer. Such an arrow degenerates to a point in the case of an azeotropic composition. A phenomenon known as "partial azeotropy" is of interest in the context of multicomponent systems, with only one of the monomers represented by an identical mole fraction in both copolymer and monomer mixture. Thus, for ternary copolymerization

$$\frac{m_1}{m_1+m_2+m_3} = \frac{[\mathrm{M}_1]}{[\mathrm{M}_1]+[\mathrm{M}_2]+[\mathrm{M}_3]} \tag{3.101}$$

A systematic computer search of the literature has produced copolymerization parameters for 37 ternary azeotropes, 4 quaternary azeotropes, and one 5-component azeotrope [912]. Figure 77 shows copolymer composition distributions (CCDs) for the monomer pairs and compositions treated in Figure 75. Copolymer of uniform composition can be expected during a batch polymerization only at the azeotropic composition, or at extremely low conversions. Strictly speaking, a copolymer is not uniform at all molecular masses even under azeotropic conditions. What is in fact produced is more nearly a

Figure 77. Copolymer composition distributions (CCDs) for the monomer pairs of Figure 75. CCDs of completely polymerized batches with molar ratios $[M_1]:[M_2] = 1:3$ (first column), 1 : 1 (second column), and 3 : 1 (third column)
The mean composition of the copolymer corresponds to that in the batch. The height of each block represents that fraction of the overall copolymer that has a composition within the block width of 0.05
Experimental data and calculated values as a function of f_1; 60 °C, [I] = 1 g/L azobisisobutyronitrile

statistical distribution about a mean [913], [914], although at high degrees of polymerization this variation is minor in comparison to the heterogeneity that results from progressive changes in the composition of the monomer mixture with conversion.

Copolymerization in an HCSTR. In an HCSTR operating at steady state the temperature and concentration are constant in both space and time. The result is therefore a chemically uniform copolymer. In the limiting case of very low conversion, the copolymer composition corresponds to the predictions of Equation (2.121) and Figure 75 when concentrations of monomer in the inlet stream are used to calculate monomer composition. The only other situation in which the composition of the copolymer corresponds precisely to the composition of the monomer mixture in the feed is the technically unrealistic limit of complete conversion, which would require impractically long residence times. The instantaneous copolymer equation, of course, can always be used when monomer composition in the exit stream is used (as opposed to inlet stream) [915], [916]. Figure 78 shows the change in steady-state copolymer composition for the system styrene/acrylonitrile (40/60) as a function of conversion. Thus, a copolymer with a particular composition can be made in practice (at least approximately) either by establishing in advance a preferred composition for

the monomer feed and then varying the extent of conversion, or by varying the feed composition at a fixed conversion.

Figure 78. Continuous copolymerization in the system styrene ($f_1 = 0.4$) / acrylonitrile ($f_2 = 0.6$) [915]
Composition of accumulated copolymer F_i as a function of conversion

Copolymerization in a SCSTR. It was noted earlier that true mixing is often less complete than envisioned by the HCSTR concept in a polymerization reactor operating under conditions of high viscosity. Most industrial reactors probably provide an efficiency of mixing that falls between the values assumed for the HCSTR and SCSTR. By introducing certain simplifying assumptions, O'Driscoll and Knorr [917] were able to calculate CCDs corresponding to the three reactor models CPFR/BR, HCSTR, and SCSTR. Figure 79 A shows a representation of a typical instantaneous copolymer composition diagram. Figure 61 B shows CCD curves for the three ideal reactor types at two conversions. The feed composition is fixed at $f_1 = 0.4$ for all cases shown. Open circles represent mean copolymer compositions F_1 which are not very different in the three cases. The differences in the CCDs are greater, however. At 35 % conversion the CCD is relatively narrow in a CPFR/BR (curve 1), absolutely uniform in an HCSTR (curve 2), and already quite nonuniform in a SCSTR (curve 3). In the latter, more than 10 % of the polymer is homopolymer of monomer 2. A SCSTR always provides several batch-reactor-like compartments with very long residence times, high conversions, and extreme changes in monomer and copolymer compositions. At 73 % conversion the CCD shows nearly as much nonuniformity with a CPFR/Batch (curve 4) as with a SCSTR (curve 6), only the HCSTR (curve 5) again producing a uniform CCD. The amount of homopolymer produced is, of course, greater at 73 % than at 35 % conversion.

Figure 79. Copolymerization of methyl methacrylate (M_1) – vinyl acetate (M_2) in three types of reactor: BR, HCSTR, and SCSTR [917]
A) Instantaneous composition, calculated with $r_1 = 20$, $r_2 = 0.015$; B) Copolymer composition distribution (CCD) at $f_1 = 0.4$, 35 and 73 % conversion in a BR (curves 1 and 4), a HCSTR (2 and 5), and a SCSTR (3 and 6)

3.3.6.1.5. Long-Chain Branching and Cross-Linking

The amounts of long-chain branching and cross-linking (with gel formation) obtained in free-radical polymerizations depend strongly on the residence-time distribution of the reactor and the conversion (or polymer concentration). Compared to the HCSTR, the CPFR/BR gives less long-chain branching, cross-linking (cross-linking density), and gel for the same conversion. Apparenty, calculations on long-chain branching and cross-linking in a SCSTR have not been performed; however, one could speculate that the extent of long-chain branching in a SCSTR would lie between that for a CPFR/BR and HCSTR. Graessley et al. [918] have carried out theoretical modeling and experiments for CPFR/BR and HCSTR using vinyl acetate homopolymerization. Their experimental polydispersity data are shown in Figure 80 for CPFR/BR and HCSTR. Note that long-chain branching is due to chain transfer to polymer and addition of polymeric radicals to terminal double bonds on polymer chains and that such branching leads to increases in the polydispersity index starting at 2.0 for linear chains produced at

low conversion (in other words, the larger the PDI, the higher the long-chain branching frequency). A survey by REICHERT and MORITZ [918] covers the effect of reactor type as well as the effect of changes in the properties of the reacting mixture on the polymerization processes. For example, the reaction mixture viscosity may increase by several orders of magnitude with conversion and this may affect kinetic rates (e.g., Trommsdorff – Norrish effect, reduction in initiator efficiency, and propagation rate constant), as well as processes of heat, mass, and momentum transfer, the quality of mixing and the residence-time distribution of the continuous process. They also point out that the reactor type (RTD and degree of segregation) can significantly affect long-branching and cross-linking levels in free-radical polymerization.

Figure 80. Polydispersity index PDI = P_W/P_N as a function of conversion for batch and CSTR bulk polymerization of vinyl acetate
a) Continuous; b) Bulk

A semi-batch process has been investigated using a comprehensive kinetic model for long-chain branching and cross-linking for the purposes of producing homogeneous polymeric networks [356], [363–365], [919], [920]. In the model, "the cross-linking/branching density distribution" was proposed. The use of the distribution enables one to calculate MWD irrespective of the reactor type [921]. This model has been successfully applied to various batch copolymerizations involving methyl methacrylate – ethylene glycol dimethacrylate and acrylamide –*N,N′*-methylene bisacrylamide. It has been shown that the variance of the cross-link density distribution is reduced with the use of a chain transfer agent. BOOTS [922] confirmed the effect of shorter primary chains qualitatively using a Monte Carlo simulation.

Figure 81. Anionic (living) polymerization of butadiene showing measured versus model-predicted heterogeneity index HI (polydispersity index PDI) [923]

Figure 82. Anionic (living) polymerization of butadiene showing the effect of RTD on heterogeneity index or breadth of MWD [923]
a) Batch/plug flow reactor; b) 2 CSTRs

The MWDs produced by living anionic polymerization, as shown earlier, are strong functions of RTD. CHANG et al. [923] used changes in RTD to modify MWD in butadiene polymerization in experiments involving a reactor train, while MEIRA et al. [924–930] used periodic operation (in residence time) to broaden the MWD as well as controlled addition of killing agent in semi-batch operation. CHANG et al. [923] developed a comprehensive model for the anionic solution polymerization of butadiene with *n*-butyllithium initiator, tetramethylethylenediamine modifier, and hexane solvent. The model successfully predicted monomer conversion, vinyl structure, and polydispersity for both batch reactors and continuous reactor trains.

Figure 81 shows predicted versus measured heterogeneity index (polydispersity index or M_W/M_N), covering the range from that obtained in a PFR or batch reactor to that obtained in a single CSTR. Figure 82 shows the polydispersity for 2 CSTRs of equal volume in series with equal conversion of monomer in each, giving the lowest value of polydispersity, 1.5.

3.3.6.2. Reactor Dynamics and Stability

Reichert and Moritz [918] discuss reactor stability and safety under the subtopics thermal and concentration stability. The strong nonlinear dependence of polymerization rate (or heat production rate) on temperature is due to the Arrhenius dependence of rate on temperature and to the large activation energy and heat of polymerization. The dynamic behavior of polymer reactors is therefore greatly affected by temperature. The influence of the nonlinear dependence of polymerization rate on monomer concentration, on reactor dynamics is much smaller than that for thermal effects. Both static and dynamic instabilities may occur when stability limits are crossed. The reactor is statically unstable if temperature and conversion rapidly move from one state to another as if alternately experiencing "ignition" and "extinction". Dynamic instabilities give rise to periodic changes in temperature and monomer conversion with certain phase shifts observed [931], [932]. Thermal instabilities may occur in various reactor types (CSTR, PFR, nonideal reactors) [933], [934]. Henderson [935] points out that for all prior publications on multiple steady states and instability for free radical polymerization in a CSTR, three basic assumptions were made:

1) The heat-transfer coefficient of the vessel wall does not change with monomer conversion
2) The viscous dissipation term for the agitation is negligible
3) Perfect mixing (ideal RTD and micromixing)

Mechanical work of the agitator can be a significant factor in the energy balance for a pilot-scale reactor (perhaps for solution and bulk polymerization, but not for suspension and emulsion polymerization), while it is almost negligible for commercial scale. Assumptions (2) and (3) may be valid for low-viscosity solution processes; however, in bulk polymerization, the viscosity can increase by several orders of magnitude and, therefore, all 3 assumptions are questionable. Henderson again points out that a thermal runaway can occur when:

1) The process side heat-transfer coefficient decreases significantly
2) The agitator provides insufficient mixing of the reaction mass, allowing hot spots to develop
3) The agitator is putting more mechanical work into the system than designed for

Ray et al. [788–791], [936–945] have made the most significant contributions to the understanding of polymer reactor dynamics and stability. Comprehensive reactor models were developed for a range of polymerization processes and reactor types: nonisothermal solution homo- and copolymerization in a CSTR [931], [939], [940]; batch and continuous emulsion polymerization reactors [788–791], [941], [942]; heterogeneous coordination polymerization for both liquid and gas dispersion reactors [943–945]. The contributions by Ray et al. are notable not only for the comprehensive mathematical models but also for attempts at experimental verification. In this regard, the experimental investigation of the effect of chain-transfer agents on the stability of continuous latex reactors is very revealing. Whereas under most operation conditions the continuous emulsion polymerization of styrene is stable, the addition of a chain-transfer agent to the recipe can lead to sustained oscillations. Some of Ray's general conclusions include:

1) Bifurcation analysis reveals a parameter space rich in dynamic phenomena. It confirms limit cycle behavior (in which monomer conversion does not smoothly approach a constant steady-state value, but rather oscillates with constant frequency and amplitude indefinitely) and analyzes the stability of periodic branches in detail providing useful guidelines for experimental design.
2) Full-scale reactors exhibit dynamic behavior of high complexity.
3) Semi-batch reactors can be operated under conditions that insure a fast approach to a

steady-state operating value, hence permitting almost perfect control. The possibility of oscillatory behavior was, however, demonstrated.

4) Multiplicity (multiple steady states) occurs under isothermal conditions due to the Trommsdorff – Norrish effect and there appears to be no relationship between phenomena causing multiplicity and reactor oscillations.
5) The PSD plays a major role in latex reactor stability. Models which calculate only a mean diameter d (and not the full PSD) cannot predict oscillations under any operating conditions.
6) Polymer particle multiplicity, which leads to polymer melting and sticking (in gas-phase heterogeneous coordination polymerization, such as UNIPOL) can cause a thermal runaway of the reactor (UNIPOL is open-loop unstable). Multiplicity and Hopf bifurcation of the fluidized-bed reactor can lead to runaway and long periods of slowly damped oscillations. The reactor is prone to runaway even under feedback control because of cooling limitations and nonlinear sensitivity to process disturbances.

Lu and Brooks [946] have confirmed that latex reactor startup policy can have a significant effect on reactor stability.

It is clear, based on these studies of reactor stability, that a comprehensive dynamic model of the polymerization reactor is required to properly design a continuous manufacturing process (process stability, control, and startup procedures should be considered at the design stage). The interactions are too complex to permit an effective design based on costly experimentation alone.

3.3.6.3. On-Line Monitoring and Control

The goals in commercial polymerizations are consistent polymer properties, high productivity, and safe operation achieved in the most economic manner possible. Polymerizations (particularly ionic and free-radical) are very sensitive to temperature and impurities (radical scavengers and poisons at ppm levels) and, therefore, adjustments may have to be made during polymerization. Process models when applied in real time require measurements and parameter updating to track and control the process. The need for monitoring the polymerization is clear and to be most effective in controlling the process, on-line monitoring is highly desirable. A survey of on-line sensors for polymerization reactors was made by Chien and Penlidis [947]. Although considerable advances have been made in polymer reaction engineering over the past two decades, sensor technology for on-line monitoring is still in its infancy. The major problem has been the on-line measurement of polymer and particle properties (copolymer composition, molecular mass averages, long-chain branching, as well as cross-linked gel content and polymer particle size distribution in suspension and emulsion polymerization). Sensors in the reaction mixture are readily fouled by sticky polymer and polymer particles. Another factor to explain the lack of progress is the fact that sensor development is a multidisciplinary task with expertise required in statistics, mathematical modeling, process understanding, reactor design, advanced control concepts, electronics, and instrumentation engineering [947]. Even the measurement of polymer properties off-line is difficult (e.g., measurement of molecular mass averages and long-chain-branching frequencies for heterogeneous copolymers [870]). Chien and Penlidis [947] classify sensors as those which monitor reactor operation [by measuring temperature, pressure, flows and level (of reaction mixture in the reactor)], and those that monitor polymer properties (e.g., by measuring density, viscosity, concentrations, copolymer composition, particle size, using densitometers, viscometers, gas and liquid chromatographs, IR and UV spectrophotometers, light scattering, ultrasonics, fiber-optic techniques, robotics, reactor energy balances, and state estimation/filtering techniques). Most of the commercial applications of on-line monitoring involve those which monitor reactor operation, although reactor energy balances are commonly used to monitor monomer conversion. The main problem with the successful use of reactor energy balances lies in the evaluation of the transient accumulation terms (time derivatives of temperature) and in accounting for the propagation of measurement errors (temperature and flow rate) into the calculated heat release term. Acceptable results are

often obtained through rapid sampling and then averaging or filtering all the measurements at regular short intervals [949].

Two promising on-line monitoring techniques are based on the use of ultrasound and NIRS (near infrared spectroscopy) [948]. Ultrasonic velocity and attenuation measurements have been used for monitoring high-temperature composition in extruders and melt-transfer lines; high-temperature imaging studies in extruders; and for ultrasonic spectroscopy of dispersions. NIRS is an older technique which has been improved by newly available computing power. It is the most promising process spectroscopy available at present because of its process compatability and ability to analyze multicomponent mixtures. NIRS has been applied as an on-line monitoring technique for both extruders used for chemical modification and polymer reactors.

The on-line monitoring and control of polymer and polymer particle properties should provide a major improvement in product consistency and productivity.

There have been a number of excellent reviews on control of polymerization reactors [947], [949], [950]. Most industrial control practice to date has centered around batch reactor sequencing and the control of process variables such as temperature, pressure, and viscosity. Reactor energy balances, as mentioned earlier, have also been used to infer polymer production rates and monomer conversion.

Much of the academic literature has focused on the computation of optimal operating policies for batch reactors by using nonlinear programming or the maximum principle [374]. These policies are open-loop in that they provide optimal feed and temperature policies versus time. Kozub and MacGregor [951] presented a much simpler solution to the optimal trajectory problems based on an "instantaneous property" approach. This latter approach is applicable only to chain-growth polymerizations (see Section 2.2 for details of instantaneous property calculations), but it allows for the feedback implementation of these optimal policies via nonlinear control.

Due to the lack of sufficient on-line sensors to monitor polymer properties of interest or because some property measurements are only available infrequently from quality control laboratories, various methods for inferring or estimating these properties on-line by using fundamental mathematical models have been proposed. State estimators such as the Kalman Filter [952], [953] and recursive parameter estimators [954] have been advocated to update model parameters and predict polymer properties.

Feedback control over measured or inferred properties in continuous reactors has been accomplished by using empirical models [955], [956].

However, in spite of the many advances that have been made in the methodology for the advanced control of polymerization reactors, there are still few industrial applications.

Figure 83. Continuous emulsion polymerization in a reactor train with a split feed (small polymer particle nucleating reactor followed by one or more larger finishing reactors) [956]
a) Small seeding reactor; b) First large reactor in train

To again emphasize the point that control problems should be considered at the design stage of a polymer manufacturing process, reference is made to the well-known stability problems that are experienced with continuous emulsion polymerization (in a single CSTR) involving monomer(s) that experience Case I kinetics (e.g., vinyl acetate and vinyl chloride). Modern control theory did not provide suitable control methodology for the single CSTR. It was decided, therefore to go back to the design stage, redesign the process by using a dynamic reactor model and minimize control problems at the design stage. The new design which is shown in Figure 83 has almost trivial control problems [949], [956]. Experimental verification of the increase in stability of this new design may be seen in Figure 84. The initial response (conversion

Figure 84. Conversion responses to CSTR reactor system shown in Figure 83 for continuous emulsion polymerization of vinyl acetate
Part A: operation with a single CSTR (shows sustained oscillations)
Part B: switching over to seed reactor followed by one finishing reactor (responses for both reactors are shown, with very stable response for downstream reactor and minor disturbance for seed reactor) [611]

versus time) is for a single CSTR. The following two responses are for the small seed reactor and for the larger finishing reactor.

1. Introduction

Electrically conducting polymers (ECPs) are materials with an extended system of C=C conjugated bonds. They are obtained by reduction or oxidation reactions (called doping), giving materials with electrical conductivities up to 10^5 S/cm. These materials differ from polymers filled with carbon black or metals because the latter are only conductive if the individual conductive particles are mutually in contact and form a coherent phase.

This review concerns the synthesis routes, polymerization techniques, doping, orientation, and development of well-defined, highly conducting polymeric materials. Their wide range of potential uses from electrodes in rechargeable batteries to organic transistors is limited by their vulnerability to air and moisture due to their highly conjugated structures and the doping agents. Electrically conducting materials are compiled, their specific properties and potential applications are described.

Numerous attempts have been made to synthesize "conductive organic materials". The first was the synthesis of polyaniline by F. GOPPELSROEDER in 1891 [1]. After decades interest grew in organic polymers as insulators, but not as electrical conductors.

In the late 1950s organic semiconductors became the focus of investigations. Preliminary studies in this field up until the mid 1960s are reviewed in [2]. The semiconducting polymers were termed "covalent organic polymers", "charge-transfer complexes", "organometallic polymers", "hydrogen-bonded polymers", and "mixed polymers". Highest conductivity values reached about 10^{-3} S/cm. In 1964 LITTLE theoretically evaluated the possibility of superconductivity in polymers and suggested a model, consisting of a polyene chain with cyanine, dye-like substituents [3]. In the same year systematic studies were presented based on aromatic and heterocyclic compounds exhibiting electrical conductivities of 0.5 S/cm [4], followed by studies correlating doping, pressure, irradiation, and chain length to conductivity, with values up to 100 S/cm [5].

Interest heightened and became acute from 1975 when IBM scientists showed that poly(sulfur nitride), $(SN)_n$, was superconductive [6] and MACDIARMID's group reported [7] the doping of polyacetylene films prepared by SHIRAKAVA [8] reaching conductivity values of 38 S/cm. Since then many expectations have been raised, but scientific progress and practical applications have been limited; they depend on the reproducible production of well-defined specimens, the determination of synthesis conditions, and the laws relating these conditions to product properties. Synthetic methods are improving; more easily processible, soluble, flexible materials are now being produced.

2. Synthetic Routes

The synthesis of electrically conducting polymers with conjugated −HC=CH− bonds requires the controlled coupling of a large number

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a21_429

of monomers (unsaturated compounds or compounds with difunctional groups). Alternatively, pendant groups attached to existing polymers can be cyclized to give conjugated systems.

Polymerization of unsaturated monomers gives polymers with long chains that are often branched and cross-linked and therefore insoluble. Alkynes polymerize as follows:

1) $n\,HC{\equiv}CH \longrightarrow \text{-}(CH{=}CH)\text{-}_n$
   insoluble polyacetylenes [9]
2) $n\,HC{\equiv}C{-}CH{=}CH_2 \longrightarrow \text{-}(CH{=}CH{-}CH{=}CH)\text{-}_n$
   insoluble polyacetylenes [9]
3) $n\,RC{\equiv}CH \longrightarrow \text{-}(CR{=}CH)\text{-}_n$
   soluble polyacetylenes where R denotes alkyl or aryl groups [10]
4) Alkyne or allene $\longrightarrow$ 460 °C thermal polymerization, insoluble polyenes and aromatics [11]

Stepwise coupling of monomers with difunctional groups runs in a more controlled fashion than polymerization of unsaturated monomers but problems are caused by low conversion rates and purification of the starting monomers. This method includes Wittig, MacMurry, retro Diels – Alder, and elimination reactions. It is accessible to a wide variety of soluble precursors and produces defined polymers. Examples follow:

1) Oxidative coupling [12] can be applied to pyrrole, thiophene, aromatic, and heteroaromatic systems (0 – 350 °C)

2) Grignard coupling [13]:

3) Boronic acid coupling [14]:

4) Stille reaction [15]:

5) Elimination reactions [16]:

6) Feast reaction (retro- cycloaddition) [17]:

7) Grubb's method: polybenzvalene is isomerized to polyacetylene in the presence of $HgCl_2$ [18]:

Cyclooctatetraene is also polymerized to give soluble polyenes [19]:

Polycyclization starts with polymers whose pendant side groups are cyclized to give condensed systems, often under pyrolytic conditions. Defects cannot be excluded.

These methods lead to the basic structures of electrically conducting organic materials (ECOMs) and are reviewed in [9]. Examples follow [12]:

Analogous reactions occur with $-CH{=}CH_2$ pendant groups.

Monomers may also be cyclized [10, 20]:

3. Principles of Electrical Conduction

The electrical properties of materials are determined by their electronic structure (Fig. 1). The band theory accounts for the different behaviors of metals, semiconductors, and insulators.

The band gap is the energy spacing between the highest occupied energy level (valence band) and the lowest unoccupied energy level (conduction band). Metals have a zero band gap which means that they have a high electron mobility, i.e., conductivity. Semiconductors have a narrow band gap (ca. 2.5 – 1.5 eV), conductivity only occurs on excitation of electrons from the valence band to the conduction band (e.g., by heating). If the band gap is larger (> 3 eV), electron excitation is difficult; electrons are unable to cross the gap and the material is an insulator [21]. Electrically conducting organic materials such as polyphenylene, polyacetylene, or polypyrrole are, however, peculiar in that the band theory cannot explain why the charge- carrying species (electrons or holes) are spinless. Conduction by polarons and bipolarons is now thought to be the dominant mechanism of charge transport in organic materials [22]. This concept also explains the drastic deepening of color changes produced by doping. A polaron (a term used in solid-state physics) is a radical cation that is partially delocalized over several monomer units (e.g., in a polymer segment). The bipolaron is a diradical dication. Low doping levels give rise to polarons, whereas higher doping levels produce bipolarons. Both polarons and bipolarons are mobile and can move along the polymer chain. See also, → Plastics, General Survey, Chap. 9.2.

Doping. The process that transforms insulating polymers (e.g., polyacetylene, conductivity 0.1 S/cm) to excellent conductors (Fig. 2) is the formation of change-transfer complexes by electron donors such as sodium or potassium (*n* doping, reduction) or by electron acceptors such as I_2, AsF_5, or $FeCl_3$ (*p* doping, oxidation). The doped polymer backbone becomes positively or negatively charged [23] with the dopant forming oppositely charged ions (Na^+, K^+, I_3^-, I_5^-, AsF_6^-, $FeCl_4^-$). The polymer can be switched between the doped, conductive state and the undoped, insulating state by applying an electric potential that makes the counterions move in and out. This switching corresponds to charging and discharging when these materials are used as electrodes in rechargeable batteries.

Figure 2. Comparison of the electrical conductivity (300 K) of organic and inorganic materials and the effect of doping

Measurement. Electrical conductance is a measure of the flow of current through a material for a given applied voltage [24].

The electrical conductivity σ in reciprocal ohms or siemens per centimeter (Ω^{-1} cm^{-1} or S/cm) denotes the current flow through a body of length 1 cm and with a cross-sectional area of 1 cm^2. The conductance σ is usually measured via its inverse, the electrical resistance R ($\sigma = 1/R$).

The resistivity is the inverse of the conductivity

$$\sigma = \frac{d}{F}\frac{1}{R}$$

(R in Ω, σ in Ω^{-1} cm^{-1}, d is the thickness of the specimen in cm, and F its surface area in cm^2).

Figure 3. Conductivity measurement equipment

Ohm's law ($R = V/I$) is valid for electrical conductors (metals) and semiconductors and allows R to be determined by measuring the applied voltage V in volts and the current I in amperes with a simple measuring system (Fig. 3) or with a Wheatstone bridge.

With high resistances (i.e., $\sigma = 10^{-4}$ to 10^{-14} S/cm), two-point measurement is enough. Higher conductivities, as in electrically conducting polymers, require four-point measurements because the contact resistances in the circuit are frequently as great or greater than that of the material under investigation.

Contactless measurements of the conductivity are possible in a microwave field [24].

4. Orientation Processes

Orientation processes are powerful methods that are used to improve conductivity and other material properties (e.g., transparency, anisotropy). Orientation can be achieved in several ways, including stretching.

Mechanical stretching can be performed after polymerization, e.g., in noncross-linked polymers [25]. In the case of polyacetylenes prepared with aged Ziegler–Natta catalysts [26, 27], stretching increases conductivity from 2500 S/cm to values as high as 10^5 S/cm.

Continuous electrochemical polymerization (e.g., of polypyrrole) on the surface of a rotating drum permits simultaneous peeling off, mechanical stretching, and orientation

$\sigma \leq 200$ S/cm [25]. Greater stretching rates and therefore greater conductivities are reported in poly(pyrrole perchlorate) films (σ up to 10^3 S/cm) [28]. Biaxially stretched films yielded conductivities of 800 S/cm parallel to the stretching direction and 290 S/cm in the cross direction. Stretched poly(phenyl vinylenes) and poly(thienyl vinylenes) yielded conductivities of ca. 10^3 S/cm [29].

Orientation can also occur during polymerization or by performing polymerization in an oriented matrix consisting of liquid crystals and using magnetic fields [30]. Variants are the use of liquid crystal matrices during the electro chemical synthesis of polyheterocycles [31] and the synthesis of polymers (e.g., substituted thiophenes) with liquid crystal side chains that contain sulfonate groups [32]. The sulfonate groups act as " self dopants" and the liquid crystal side chains are responsible for orientation.

Polymerization of extremely thin polyacetylene films (< 1 µm) on crystal surfaces by epitaxial growth (e.g., on frozen benzene) [33] also induces orientation in the deposited polymer layer. Substituted polypyrrole films with a high anisotropy can be produced by the Langmuir–Blodgett technique [34–36].

5. Types of Electrically Conducting Organic Materials

Electrically conducting organic materials can be divided into three main groups: polyenes, polyheterocycles, and polyaminoaromatic compounds. Polyacetylene, polypyrrole, and polyaniline are the most intensively studied polymers.

5.1. Polyacetylene

Polyacetylene (PAC) exists in various isomeric forms:

cis-transoid (*cis*-polyacetylene)
[*25786-70-1*], [*74373-36-7*]

trans-cisoid
[*73589-68-1*]

trans-transoid (*trans*-polyacetylene)
[*25768-71-2*]

cis-Polyacetylene is relatively unstable and reverts to the thermodynamically stable *trans*-polyacetylene via the metastable *trans*- cisoid form. *cis*- cisoid PAC has not yet been prepared in pure form, it has a cyclic, helical structure [37].

The term "polyacetylene" was first mentioned in 1866 [38]. In 1898, E. Erdmann and P. Köthner [39] described a "high-molecular-weight copper acetylene" that was formed when acetylene gas was passed over copper powder below 250 °C. In 1948 Reppe [40] prepared Cuprene film with a metallic luster. In 1961 Hatano reported the polymerization of acetylene with a $AlEt_3/Ti(OBu)_4$ catalyst to give polymers with conductivities up to 0.001 S/cm [41]. Since then intensive work has been carried out on the various polymer types, reviews are given in [42]. Some important syntheses are listed in Table 1. Table 2 shows the conductivities of various types

The polyacetylenes grow primarily in the form of fibrils with an internal surface area of up to 200 m^2/g [45]. The fibrils are insoluble and can be rendered electrically conductive by incorporation of *n*-type or *p*-type dopants.

The polyacetylenes are chemically unstable and react, for example, with atmospheric oxygen to form epoxy, carbonyl, or carboxyl groups. $N-(CH{=}CH)_n$ compounds are more stable, probably due to the absence of defect sites at high crystallinity. Conductivity increases as a function of crystallinity and decreases as a function of defects (sp^3-bonded carbon atoms, $-CH_2CH_2-$) [46].

Figure 4 illustrates two types of polyacetylene. The standard Shirakawa type (Fig. 4A) is cross-linked and contains ca. 2 % sp^3 fractions. The new BASF technique involves polymerization at room temperature (instead of -76 °C) and the use of a tempered catalyst. The stretched polyacetylene product has parallel fibrils (Fig. 4B). It is linear (no sp^3 frac-

Table 1. Preparation and properties of polyacetylenes

BASF polyacetylene with additional reducing agent, oriented [44]	120 000 [c]	1.15 (0.90)	104 347

[a] Doped with $FeCl_3$. [b] Doped with I_2 vapor. [c] Doped with a saturated solution of I_2 in CCl_4. [d] Densities for polymers denote values after doping; values before doping are given in parentheses.of polyacetylenes and compares them with those of metals.

tions), is highly orientable (can be stretched by up to 660 %), and has a conductivity exceeding 10^5 S/cm. A convincing demonstration of the high anisotropy (1: 100) in the stretched samples is the fact that when strips of such a stretched polymer are laid across each other, polarized light (sunlight) is extinguished in the region of overlap [47].

Substituted Polyacetylenes. The synthesis of polymers from substituted acetylene monomers is directed toward the preparation of substituted, conjugated chains which ameliorate the negative properties of polyacetylenes (e.g., sensitivity to air, insolubility, and infusibility) while maintaining the desired electrical properties of acetylene's conjugated backbone [10, 48]. Alkyl- and aryl-substituted polymers result. They are soluble (e.g., in toluene and cyclohexane) and processible, but have low conductivities (< 0.1 S/cm) compared with the unsubstituted polyacetylene.

Figure 4. Scanning electron micrographs of iodine-doped polyacetylene
A) Standard, cross-linked polyacetylene (conductivity ca. 500 S/cm); B) Stretched polyacetylene (conductivity > 100 000 S/cm)

Modification of Polyacetylenes. The controlled modification of the polyene chain by radical reactions and Diels – Alder addition leads to functionalized systems with slightly improved atmospheric stability but diminished conjugation length and electrical conductivity. Examples include reaction with tosylmethyl isocyanide ($TosCH_2-N{=}C$) to give polyenes with pyrrole units [49], with nitrogen-substituted spin-labeled compounds to give spin labels (e.g., maleimido peroxyl groups) [50], with chlorosulfonyl isocyanate to give $-SO_3$ and $-COO^-$ groups [47], with tetrachloromethane to give $-Cl$ and $-CCl_3$ groups [27], and with 3-chloroperbenzoic acid to give epoxy groups [27]. Cycloaddition with 3,4-dichloromaleic anhydride leads to a fusible polyacetylene (165 – 180 °C) [47].

5.2. Polydiacetylenes

In contrast to polyacetylene, polydiacetylenes [*27987-87-7*] have limited electrical conductivity (≤ 0.1 S/cm), but can be obtained as large, single crystals.

The polymerization of diacetylene

is an example of a topochemical polymerization in which 1,4-addition of 1,3-diyne units takes place in the crystalline state. The reaction does not require a catalyst and is performed by irradiation of the diacetylene crystals with visible or UV light, X-rays, or γ-rays, or by annealing the crystals below their melting point. The unreacted monomer is then extracted with a suitable solvent (e.g., hexane, toluene), leaving a single, dark red crystal of polydiacetylene. This unique polymerization process was already observed in 1882 [51] and has now been intensively studied [52]. A correct interpretation of the phenomena was first provided in the early 1970s [53].

5.3. Polypyrrole

Polypyrrole [*30604-81-0*] is a polysalt that can be produced in the form of powders, coatings, or films; it is intrinsically conductive.

Synthesis. The preparation of polypyrrole (pyrrole red and pyrrole black) by oxidation of pyrrole dates back to 1888 [54] and by electrochemical polymerization to 1957 [55]. A fairly long period elapsed before this organic π-system attracted general interest and was found to be electrically conductive [4].

Conductive polypyrrole films are obtained directly by anodic polymerization of pyrrole in aqueous or organic electrolytes (acetonitrile) [56]. They are black and, under suitable reaction conditions, can be detached from the anode in the form of self-supporting films (minimum thickness ca. 30 µm). Some of the conducting salt used in the electrolyte solution is incorporated in the film as a counterion.

In contrast to polyacetylene, polypyrrole has a high mechanical and chemical stability and can be produced continuously as flexible film (thickness 80 µm; trade name: Lutamer, BASF) by electrochemical techniques (Fig. 5) [57].

Figure 5. Continuous electrochemical process (BASF) for producing polypyrrole on a rotating drum electrode

Other electrochemically polymerizable heterocycles are thiophene, furan, and their substituted and oligomeric derivatives.

The polymerization reaction is very complex. The main reaction steps are shown in Figure 6 [58]. A radical cation is formed in the initial oxidation step. This is followed by a coupling reaction, deprotonation, and a one-electron oxidation which regenerates the radical cation system. Also important is the reaction introducing oxygen with formation of a labile −CONH group in the ring system.

Figure 6. The oxidative coupling of pyrrole [58]

The quality of the polymers is greatly influenced by many factors, e.g., impurities, electrode material, pressure, concentrations, temperature, and comonomers. The most decisive, however, are the current density and the electrolyte, particularly the conducting anion X^- [59] because it is incorporated into the polymer as a counterion.

The properties of the counterion (e.g., its size, geometry, charge) influence the properties of the polymer. The amount of counterion (anion) incorporated depends on the reaction conditions. In general, one anion is incorporated for every three pyrrole units. Exceptions are pyrrole- or thiophenesulfonic acids where the counterion is coupled directly to the monomer (self doping) [60]. Some typical conducting anions are fluoroborate, perchlorate, aromatic sulfonic acids, penicillin, *n*-dodecyl sulfate [59,61], phthalocyanine sulfonic acid, poly(styrene sulfonic acid), camphor sulfonic acid, styrene sulfonic acid, and heparin [52].

By changing reaction conditions, polymers with different surface morphologies, (e.g., an open porous structure) can be obtained.

The anion X^- can also be released, e.g., by applying a negative potential. Release can be specifically controlled, offering interesting possibilities for active counterions of medical interest (e.g., heparin and monobactam) that are incorporated into polypyrrole.

Variation of the monomers and their substituents yields polymers with conductivities between 10^2 and 10^{-4} S/cm [59]. Alkyl substituents also increase the solubility of the poly-

mers with the result that electrically conducting polymers can be applied as coatings from solutions. This also applies to polymers derived from bridged pyrroles. Examples follow [62]:

An interesting variant is the chemical oxidation of heterocycles (e.g., thiophene or pyrrole [63]) dissolved in an organic solvent (e.g., ethanol) on the surface of various materials. Conductive coatings (thickness 0.01 μm) can be produced on films of poly(phenylene sulfone), block copolymers of butadiene and styrene (Ultrason, Styrolux), poly(vinyl chloride), or other polymer films to give transparent, antistatic films with conductivities of about 0.001 S/cm. Ceramics and glass can also be coated in this way. Porous material (e.g., wood, fabrics, and open-celled foams) or fibers (e.g., polyamide, glass, or carbon fibers) can also be modified and rendered antistatic by this method.

Conductive powders (e.g., polypyrrole) with particle sizes of about 0.1 μm and conductivities of up to 10 S/cm can also be produced by chemical oxidation and can be incorporated as fillers in thermoplastics. These materials can be used for chip carriers.

Potential Uses. The conductivity of polypyrrole film suggests applications such as flexible conductive paths in printed circuits, heating films, and film keyboards.

Polypyrrole films show good electromagnetic shielding effects of about 40 dB over a wide range of frequencies (0 – 1500 MHz).

Although the new systems appear to be promising, stability problems may be encountered. High mechanical stability and/or stable conductivity are required under a variety of conditions (e.g., presence of air and moisture, temperature, and duration of exposure). Polypyrroles in which the counterion is 4-hydroxyphenyl sulfonic acid do not undergo any change in conductivity if they are exposed to nitrogen for two months at 140 °C. No change in conductivity was observed when these polymers were stored in the laboratory for three years at room temperature and 55 % R. H. Polypyrrole is sensitive to moisture because this leads to leaching of the counterion and thus to a decrease in conductivity. This can be avoided by use of appropriate hydrophobic or polymeric counterions [e.g., camphor sulfonic acid or poly(styrene sulfonic acid)] or by incorporating hydrophilic compounds. Polypyrroles obtained by synthesis in aqueous electrolytes maintain their conductivity at a level of about 20 S/cm. Polypyrroles with perchlorate as a counterion are unstable under atmospheric conditions but can be used as electrodes in rechargeable batteries [63].

The redox character of polypyrrole was first studied in 1975 [64]. It is a suitable electrode material for rechargeable electrochemical cells. The advantage of polymer electrodes is that they can be easily shaped, allowing novel battery designs (e.g., for the electronics sector) and less expensive production methods. Polymer cells with polypyrrole and lithium electrodes have been developed (Fig. 7) [63]. In the flat cell, the polypyrrole and lithium films are sandwiched together; in the cylindrical cell, the two films are wound concentrically. Their energy per unit mass and their discharge characteristics are similar to those of the nickel – cadmium cells now on the market. More than 500 charging and recharging cycles have been achieved with laboratory cells. Applications include dictaphones and pocket radios [63].

Figure 7. Electron reactions of a rechargeable polypyrrole – lithium battery
During discharge electrons flow from the negative electrode to the positive electrode and reduce the polypyrrole from the doped to the neutral state. During recharging an opposite potential is applied to the electrodes. The polymer takes up BF_4^- ions from the electrolyte and is oxidized. Lithium ions are also deposited at the other electrode.

5.4. Polythiophene

Since the first report of thiophene polymerization in 1883 [65] decades passed until thiophene was considered to be an attractive monomer for conducting polymers [66]. Interest is still growing because thiophene is easier to handle than pyrrole (less sensitive to oxygen) and allows the simple preparation of substituted monomers leading to soluble polymers. Three methods have been used to produce polythiophene [*25233-34-5*]: chemical oxidation (Lewis acid), coupling with organometallic agents or by the Grignard reaction, and electrochemical oxidation (anodic). The preparation techniques for films, powders, and coatings are similar to those of pyrroles but thiophene needs stronger oxidants for its polymerization than pyrrole or other heterocycles. Standard oxidation potentials follow:

Pyrrole	+0.8 V
Indole	+0.9 V
Azulene	+0.9 V
Thiophene	+1.6 V
Furan	+1.85 V

The oxidation potential of the monomers correlates to the ease of polymerization.

Figure 8 illustrates the correlation between UV – VIS absorption and the oxidation potential of thiophene oligomers [67]. The oxidation potential of the series $(\text{thiophene})_n$: $n = 1 - 6$ decreases with the increasing number of thiophene units.

Figure 8. Correlation between maximum absorption wavelength (a) and oxidation potential (b) of thiophene oligomers Oxidation potential measured in 0.5 mol/L Et_4NBF_4 in acetonitrile versus saturated calomel electrode.

Substituted Polythiophenes. Alkyl-substituted thiophenes with alkyl chains up to C_{18} yield polymers that are soluble in common organic solvents with electrical conductivities up to 100 S/cm. Due to their good processibility [68] and high chemical and electrochemical stabilities in air and moisture, polythiophene and its derivatives are excellent candidates for practical applications (e.g., display devices, electrochromic devices [69], energy storage, field transistors [70], solar energy cells, and overchargeable batteries [66].

5.5. Polyphenylene

Synthesis. First attempts to prepare polyphenylene [*9033-83-4*], [*24991-24-0*], [*25190-62-9*], [*26499-97-8*] date back to 1842 [71]. Riese describes a process in which polyphenylene (n=13) is synthesized from 1,4-dibromobenzene and sodium. Further methods are the Ullmann reaction, thermal decomposition of diazonium salts, coupling of phenylene dihalogenide – Grignard compounds [72], and the oxidative coupling of benzene with $AlCl_3$ and $CuCl_2$ (Kovacic method [73]). In 1963 the Kovacic method was systematically extended by varying reaction conditions (temperature, catalysts, Lewis acid, and oxidants) and starting materials [4]. Many side reactions occur leading to cross-linked graphite-like lattices.

Other aromatic compounds, substitution products, condensed systems (e.g., diphenylene, terphenylene, pyrene, anthracene, chrysene), unsaturated

cyclic compounds (e.g., cyclopentadiene, cyclooctatetraene), heterocyclic compounds (e.g., thiophene, pyrrole, quinoline), and metal complexes (e.g., phthalocyanines, ferrocene) were investigated.

All Friedel – Crafts catalysts and the usual dehydrogenation agents can be used for oxidative coupling. Oxidizing Friedel – Crafts

agents, such as $FeCl_3$, assume both functions. The degree of suitability has been tested on benzene/$CuCl_2$ (Eq. 1) and on benzene/$AlCl_3$ (Eq. 2).

$$AlBr_3 > AlCl_3 > FeCl_3 > MoCl_6 > NbCl_5 > TiCl_4 > SnCl_4 > BF_3 > ZnCl_2 \quad (1)$$

$$Pd\,(II) > Co\,(III) > Mn\,(III) > Cu\,(II) > Fe\,(III) > \text{chloranil} > V\,(III) > I_2 \quad (2)$$

The oligomeric and polymeric reaction products were also characterized in terms of thermoelectric power, dark conductivity, and photoconductivity. They showed electrical conductivities up to 0.1 S/cm, the highest value obtained at that time [4]. The polymers were obtained as powders and were processed by press sintering. Later synthesis by Diels – Alder [74] or boronic acid coupling [75] lead to soluble or meltable materials.

A novel route to high molecular mass poly(*p*-phenylene) is based on the polymerization of derivatives of 5,6-dihydroxycyclo-1,3-hexadiene, a compound that is easily prepared by the bacterial oxidation of benzene [76].

The advantage of this process is that it involves a soluble precursor polymer, which means that films can first be cast, objects coated, or fibers spun from solution; poly(*p*-phenylene) is then formed on heating.

The Marvel method is similar to the Kovacic method [77]:

Properties. The properties of polyphenylenes depend mainly on their linkage (*m-, p-*), but also on the method used to prepare them. *o*-Polyphenylenes are unknown: *m*- and *p*-polyphenylenes are crystalline (> 50 %), intractable, and insoluble. *p*-Polyphenylenes are stable up to ca. 500 °C in air and up to 650 °C under nitrogen (10 % weight loss); the stability of *m*-polyphenylenes is approximately 200 °C lower [78]. Figure 9 demonstrates the drastic differences between *m*- and *p*-substituted polyphenylenes. The *para* derivatives are soluble in toluene up to $n = 6$, the *meta* derivatives are soluble up to $n = 16$. Polymer powders can be processed by press sintering (400 °C, > 100 bar).

Figure 9. Correlation of the melting points and the degree of condensation (n) of *m*- and *p*-polyphenylenes

Poly(*p*-phenylene) can be *n*-doped with electron donors or *p*-doped with electron acceptors, electrical conductivities reach 10^2 S/cm. Donor doping is best accomplished with the aid of an electron-transfer agent (e.g., by adding naphthalene or α-methylstyrene in tetrahydrofuran) [79, 80]. Acceptor doping is usually done by exposing the powders to AsF_5 gas or heating with

nitromethane solutions of SbF_5. Electrochemical doping (anodic oxidation or cathodic reduction) is performed in suitable electrolytes (e.g., acetonitrile), the electrodes being separated by diaphragms.
Anodic oxidation:

$$p\text{-PP} + AgBF_4 \longrightarrow p\text{-PP}^+BF_4^- + Ag^+$$

Cathodic reduction:

$$p\text{-PP} + LiClO_4 \xrightarrow{+e^-} p\text{-PP}^-Li^+ + ClO_4^-$$

PP = polyphenylene
Oxidation potentials, conductivities, and spectra of polyphenylene are cited in [79]. Soluble, substituted polyphenylenes and polyaromatic systems are discussed in [81].

Potential Uses. Poly(*p*-phenylene) can be used as electrodes for rechargeable batteries.

5.6. Poly(Phenylene Sulfide)

Poly(*p*-phenylene sulfide) [*9016-75-5*], PPS, (white powder, T_g 92 °C, *mp* 270 – 290 °C, 65 % crystallinity) was the first melt-processible polymer to be doped with strong electron acceptors (e.g., AsF_5) to yield highly conductive products [82]. The first laboratory synthesis of PPS was reported by MACALLUM [83] and involved the melt reaction of 1,4-dichlorobenzene, sulfur, and sodium carbonate. A commercially product has been available as powder, film, or fiber since 1973 from Phillips Petroleum under the trade name Ryton; it is produced from 1,4-dichlorobenzene and sodium sulfide (high-pressure process) in a polar solvent (*N*-methylpyrrolidone) [84].

Another process involves self condensation of a halogenated thiophenol resulting in "head-to-tail" polymerization [85]:

Poly(*m*-phenylene sulfide) and substituted (methyl-, fluoro-) poly(*p*-phenylene sulfide) are prepared by analogous reactions from appropriate monomers.

Doping of PPS with AsF_5 produces conductivities up to 2×10^{-2} S/cm [86]. Attempts to make *n*-doped PPS have been unsuccessful. In addition to AsF_5, doping with $FeCl_3$, H_2SO_4, $HClO_4$, FSO_3H, CF_3SO_3H, $AlCl_3$, TaF_5 has been investigated [87]. Heavily doped PPS undergoes intramolecular cross-linking to form benzothiophene rings [79]:

Poly(phenylene sulfides) are used where resistance to heat and chemicals is required, for example in the chemical process industry (pump housings, impellers, valves, metering devices, tanks, coil bobbins). See also, → Polymers, High-Temperature, Chap. 5.

Poly(*p*-phenylene selenide) [*52410-66-9*] and poly(*p*-phenylene telluride) [*84174-18-5*] have been prepared by techniques similar to those used to prepare PPS [79]. Conductivities of AsF_5-doped samples reach 0.01 S/cm.

5.7. Poly(Phenylene Vinylene)

Poly(*p*-phenylene vinylene) [88] [*96638-49-2*], [*87092-55-5*], [*26009-24-5*] was first synthesized by the Wittig condensation of terephthaldehyde and *p*-xylene bis(triphenylphosphonium) chloride. The method which is now mainly employed starts from a soluble polysulfonium salt [89], for example:

The polysulfonium salt is obtained by the reaction of α,α'-dichloro-*p*-xylene with excess dimethyl sulfide (50 °C, 20 h), and polymerization with sodium hydroxide (0 °C, 1 h). The first doped poly(phenylene vinylene) was reported by KARASZ using AsF_5 as dopant [90]; its conductivity was 3 S/cm. Stretching the precursor film at high temperature and doping with AsF_5 and SO_3 yielded conductivities up to 2800 S/cm [36,91].

Substituted derivatives [92], copolymers [93], and blends [94] show better thermal stability. Highly conductive graphite films have been prepared by pyrolysis of poly(phenylene vinylene) (> 3000 °C), stretched samples doped with SO_3 had conductivities of 10^5 S/cm [95]. Poly(phenylene vinylene) can be used as tunable polymer diodes or luminescent electrodes [96].

5.8. Polyaniline

The synthesis of polyaniline [*25233-30-1*] is remarkably simple and is summarized in Figure 10 [97,98]. Aniline can be chemically (1863, LIGHTFOOT) or electrochemically (1865, LETHEBY) oxidized and dehydrogenated to form a quinone diimine.

Oxidation of the primary aromatic amine usually does not stop at the monomeric quinone imines but gives rise to more complex quinone imine products. The type of product depends largely on the oxidants and the reaction conditions. 1,4-Benzoquinone-4-imino-1-phenylimine is an unstable intermediate which reacts with further aniline molecules and oligomerizes to give the final product, polyaniline.

Studies on polyaniline suggest that the polymer can exist in a wide range of structures [99], which can be regarded as copolymers of reduced (amine) and oxidized (imine) units of the form:

When $0 < y < 1$ these structures are poly(*p*-phenylene amine imines), in which the oxidation state of the polymer increases with increasing content of the imine form. The fully reduced form ($y = 1$) is leucoemeraldine, the fully oxidized form ($y = 0$) is pernigraniline, and the 50 %-oxidized structure ($y = 0.5$) is emeraldine. Each structure can exist as the base or as its salt, formed by protonation. Four repeating units can therefore be envisaged in the polymer chain in amounts which depend on the degree of oxidation and protonation of the structure. The " metallic state" is

The reaction of aniline to "aniline black" proceeds through a number of intermediates [98]:

Emeraldine is very stable and can be directly prepared from aniline by oxidation with sodium perchlorate or V(III) chloride [100]. Nigraniline and pernigraniline are further oxidation products of emeraldine, both are very unstable. The structure of emeraldine and related molecules is described in [101].

Nitrogen- or ring-substituted homologues of aniline can apparently be oxidized similarly, yielding corresponding "aniline blacks".

Figure 10. Products of aniline oxidation formed at different pH values

Oxidants used for preparing oligomers and polymers of aniline include $Cr_2O_7^{2-}$, $S_2O_8^{2-}$, Ce^{4+}, and Pb^{4+} ions. Aniline can also be polymerized by anodic oxidation.

The reaction conditions (temperature, duration, pH, oxidants, and catalysts) determine the yield and type of oxidation product [97].

A decisive handicap in the production of polyaniline is the formation of small quantities of carcinogenic benzidene (Fig. 10) [102].

Honzl synthesized benzidene-free polyanilines by avoiding the use of aniline as the starting monomer [103]:

Similar structures can be obtained by polycondensation of quinones and aromatic amines [104].

Properties. The conductivity of polyaniline is 10 S/cm up to pH 4, but decreases to 10^{-10} S/cm above pH 4. The polymers are stable up to 250 °C (undoped) and up to ca. 150 °C (doped). Conduction in polyaniline can be accounted for in terms of electrons hopping under the assistance of proton transfer, for which the presence of water plays an essential role [105].

In contrast to other electrically conducting polymers, polyanilines may be doped with protons. Polyaniline is available as powder, film, or fibrils (Versicon, Allied Signal) [106, 107].

The electrochemistry of polyanilines was first investigated at the end of the nineteenth century. In the mid 1960s, interest in this topic was renewed. The use of polyaniline as a battery electrode on account of its redox and proton transfer behavior was described in 1968 [108]. In 1986, polyaniline was presented as a "novel conducting polymer"; its preparation and redox behavior were described [109]. The phenomena of anodic oxidation and discharge by means of reversed polarity have been known since 1891 [1].

Uses. Polyaniline is primarily of interest as an electrode material. Its discharge capacity is greater than that of polypyrrole(+)/perchlorate(−), its self-discharge is higher than that of polythiophene or Ni/Cd battery systems [66]. Genies has announced a rechargeable battery based on polyaniline (anode), propylene carbonate – $LiClO_4$ (electrolyte), and Li – Al (cathode) [110, 111]. This polyaniline is made by oxidizing aniline with ammonium persulfate in ammonia/2.3 mol/L hydrogen fluoride as solvent. The

discharge capacity of the polymer is 100 A · h/kg at 25 °C and 140 A · h/kg at 40 °C for current densities of 0.5 mA/cm^2 and for an amount of material giving a capacity of 10 mA · h. The voltage in open circuit for the fully charged battery developed by GENIES is 3.6 V. The average utilizable potential is 2.8 – 3 V. The energy density for the polymer lies between 280 and 420 W · h/kg. Its behavior with regard to self-discharge and to constant applied voltage (floating life) is excellent [111]. Like polypyrroles, polyanilines show excellent antistatic behavior and have a high shielding efficiency for electromagnetic interference.

5.9. Miscellaneous Polymers

There has been a flood of literature concerning new electrically conducting polymers, examples are listed below.

Bridged macrocyclic complexes [81] are mainly derivatives of tetraazaporphyrin or phthalocyanine:

Tetraazaporphyrin (M = H_2)

Phthalocyanine (M = H_2)

The synthesis and doping of bridged phthalocyanine polymers is illustrated in Figure 11. The bridging ligand can be linked by two σ bonds, by two coordinate bonds, or by one σ and one coordinate bond (Fig. 12).

After doping with iodine, conductivities up to 10.1 S/cm are obtained. Substituted phthalocyanines are soluble and can be cast as films or handled by the Langmuir – Blodgett technique to give ultrathin, well-defined molecular layers. The insoluble powders can only be processed by press sintering.

Polyazulene [*82451-56-7*] [112, 113] is synthesized by electrochemical polymerization with ClO_4^- as counterion (similar to that of polypyrrole) yielding amorphous polymer films which can be peeled from the anode. Conductivity is 0.01 S/cm. The films may be electrochemically and reversibly discharged to the nonconducting form.

Polycarbazole [*51555-21-6*] [113]. Solutions of carbazole in acetonitrile may be electrochemically oxidized (counterion ClO_4^- or BF_4^-) at a platinum anode to give electrically conductive films with poor mechanical stability and conductivities up to 0.001 S/cm. Polycarbazole has also been obtained by vacuum evaporation of carbazole and by chemical condensation [114].

Polyindole [*82451-55-6*] [48]. Electrochemical oxidation of indole (counterion ClO_4^- or BF_4^-) yields brittle films with conductivities of ca. 0.01 S/cm. Polyindole has been employed as a polymer coating in a glucose sensor [113].

Polypyrene [*41496-25-7*] [113]. Electrochemical oxidation of pyrene (counterion BF_4^-, ClO_4^- or AsF_6^-) yields insoluble, brittle films with conductivities up to 1 S/cm.

Figure 11. Synthesis and doping of bridged phthalocyanine polymers

Figure 12. Construction of bridged macrocyclic transition-metal polymers

Polyazepine [*115483-32-4*] [115]. Phenyl azide can be photopolymerized in the gas phase to yield films of poly-1,2-azepine with a conductivity of 10^{-2} S/cm (after I_2 doping).

Polyfulvenes [*107889-59-8*] [116]. Polyfulvenes are formed by cationic polymerization of 6,6-dimethylfulvene followed by chemical or electrochemical dehydrogenation, conductivity 10^2 S/cm (after I_2 doping).

Low-band-gap aromatic polymers [117]. An important prerequisite for obtaining low-band-gap polymers is that the ground state of the polymer has a quinonoid contribution. These polymers have the general formula:

X, Y = SO_2, SO, S, N−R, CH=CH

Benzenoid and anthracenoid precursors are:

Low- or narrow-band-gap systems (gap < 0.5 eV) already contain a high proportion of thermally excited electrons at room temperature. These materials can be oxidized electrochemically at a low oxidation potential to give conducting polymers. Cross coupling with organometallic intermediates affords the undoped polymers. Conductivities up to 10 S/cm are reached (after iodine or electrochemical doping).

Polyindophenines [*138309-48-5*] [118] are prepared by reaction of isatin with thiophene and have conductivities up to 10^{-2} S/cm without additional dopant. The polymers are soluble in dimethyl sulfoxide and can be cast as films; the material is thermostable up to 230 °C.

Charge-transfer complexes [119] are combinations of electron donor compounds with electron acceptor compounds. They are synthesized, for example, by electrochemical charging of aromatic hydrocarbons with ClO_4^-. The charge-transfer complexes are assembled in defined stacks and have conductivities up to 10^3 S/cm, in some cases with superconductivity. Examples are given below [120, 121]:

Bisethylene dithiotetrathiofulvalene – I_3 complex
T_c 8.1 K

Dicyanodiimine quinone–copper complex
$\sigma = 10^3$ S/cm

Finally it should be remembered that all electrically conducting organic materials are due to the various dopant charge-transfer complexes [123].

Buckminsterfullerene [*99685-96-8*] [122] is an allotrope of carbon (Fig. 13). When doped with potassium, it reaches conductivities up to 500 S/cm; cooling to 18 K makes it superconducting.

Figure 13. Potassium-doped C_{60} molecules

6. Uses

Few of the organic materials discussed above have been demonstrated to be sufficiently stable for critical applications.

Stability is a relative property and is the "Achilles heel" of electrically conducting polymers. For example, polypyrroles with BF_4^- as counterion are unstable under atmospheric conditions but are as stable as Ni/Cd electrodes in rechargeable batteries. It was hoped that electrically conducting organic materials could combine conductivities comparable to those of metals with the processibility of plastics. Work over the last decades has gone a long way in this direction but there are still many obstacles to be mastered before these materials become widely used.

Polyene chains with extended double bond systems are unstable against oxygen, forming epoxy, carbonyl, and carboxyl groups. They also undergo cross-linking and substitution reactions (Diels – Alder and radical reactions). Aromatic and heterocyclic structures are much more stable against environmental conditions (e.g., temperature, irradiation).

Doped materials (*n* or *p* doped) are saltlike compounds and are therefore unstable against humidity, oxygen, and temperature. Conductivity is lost as a result of interruption of the conju-

gation system, this destroys the charge-transfer complexes within a few days.

Defect-free oriented polyacetylenes are more stable, they do not loose any conductivity for 3 months [24]. Polypyrroles and polythiophenes show unchanged conductivities over several years (Sections 5.3, 5.4). Polyindophenines are "intramolecularly doped", containing covalently bonded electron donor and acceptor groups within the same molecule (Section 5.9).

How many uses do conducting polymers have? The short answer is "scarcely any" [123], but they do have some applicability [80, 124, 125] for:

1) Rechargeable batteries [120, 126] (Sections 5.3 and 5.4)
2) Coatings for electromagnetic radiation shielding or electrochemical metallization [63, 127]
3) Semiconducting devices and photovoltaics [128]
4) Catalysis [129]
5) Sensors and electrochromic displays [130], e.g., for gas detection (NH_3, CO_2)
6) Solar energy conversion, e.g., electroluminescence [131]

It seems that this class of electrically conducting materials will form the basis for a new generation of "intelligent" material systems [132].

Polymers, High-Temperature

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey ; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated in Plastics, Properties and Testing . Fundamental aspects of polymerization reactions are treated in Polymerization Processes.

1. Introduction

Definition. Any definition of a *high-temperature polymer* is necessarily arbitrary. Today's conventional engineering plastics [e.g., nylon, poly(ethylene terephthalate)] were yesterday's high-temperature polymers, and the quest for improved temperature performance is ongoing. In the context of this review, thermoplastic polymers exhibiting useful mechanical properties at temperatures in excess of 150 °C would seem an appropriate description.

Various other synonyms such as *high-performance polymers* or *advanced engineering polymers* have been employed. These materials are characterized by relatively low-volume sales compared with conventional engineering polymers and a relatively high selling price. Thus the ratio of the sales price for nylon to the sales price for the high-temperature polymers considered here varies from about 1 : 3 to 1 : 20. However, these polymers enjoy applications in varying market sectors such as the electrical–electronic, automotive, aerospace, and chemical process industries because they offer good performance to cost ratio.

The fact that the polymers can be used at high temperatures should not disguise that they possess many other useful and interesting proper-

ties. The crystalline polymers, polyetheretherketone and poly(phenylene sulfide), for example,find many room-temperature applications as a result of their good environmental resistance, particularly to solvents.

Classification. As with all polymers, high-temperature polymers fall into two classes, amorphous and (semi)crystalline. Polysulfone (PSU), poly(ethersulfone) (PES), and polyetherimide (PEI) are amorphous whereas poly(phenylene sulfide) (PPS), polyetheretherketone (PEEK), and polyetherketone (PEK) are semicrystalline.

Despite the high linearity of the sulfone polymers (100 % 4,4′-specificity), the differences in the conformations of the phenyls bordering the sulfone and ether links preclude close packing of chains whereas the regular conformations of the phenyls in chains of PPS, PEEK, and PEK lend themselves to crystal formation. Interestingly, the ether and carbonyl moieties in PEEK are crystallographically equivalent.

Crystalline polymers (particularly filled grades – glass, carbon, mineral) retain useful mechanical properties above their glass transition temperature (T_g). Thus, although PEEK has a T_g of 143 °C its continuous service temperature (CST) is 250 °C. A further advantage of the crystalline range is inertness to aggressive media: PEEK shows outstanding resistance to aqueous acids, alkali, and organic solvents.

History [1]. Two synthetic routes lend themselves to the production of high-temperature polyaromatics: polycondensation (nucleophilic) or electrophilic processes. All of the polymers considered here may be made by polycondensation, and are currently manufactured by this process. Initially, electrophilic routes to PES (ICI) and various polyketones were developed but were quickly superseded by the polycondensation process, largely due to the lack of selectivity for linear polymers and the corrosive reactants used in the electrophilic process.

Raychem in 1972 launched their version of PEK (Stilan) produced via electrophilic chemistry, but this material was short-lived in the marketplace. Development of electrophilic processes continued, and polyketones were announced by Du Pont (PEKK), and BASF (Ultra PEK).

Routes to PPS (Philips), PES (ICI), and PSU (Union Carbide, now produced by Amoco) were developed during the 1960s with commercial launch in the early 1970s. Similarly, polycondensation routes to PEEK (ICI), PEK (ICI), and PEI (General Electric, GE) were developed in the 1970s with launches in the 1980s.

To put the timescale of one of these developments into perspective, ICI research for routes to polyketones started in 1972. The first 20 g sample of PEEK was made in ICI laboratories at Welwyn Garden City in 1977, followed quickly by scaleup to semitechnical quantities. PEEK manufacture moved to full production scale at Hillhouse in late 1978 and became commercially available in 1981. A dedicated plant for PEEK production was brought on-line at Hillhouse in 1987.

One of the keys for success for polymers made by polycondensation is the use of high-purity monomers to guarantee the high degree of reactivity required (> 99 %) for useful molecular masses, and the high degree of stereospecificity for properties such as toughness. Indeed, the history of the development of high-temperature polymers is mirrored by the development of their component monomers.

Stability. High-temperature thermoplastic polymers which have found commercial application have done so because they can be processed using conventional techniques such as extrusion or injection molding. However, for these materials to stand the processing temperatures employed they must exhibit stability against degradation. Typically an amorphous polymer is processed at 130 – 150 °C above its T_g and a crystalline polymer at 30 – 50 °C above its crystalline melting temperature (T_m). Thus, PES (T_g 225 °C) and PEI (T_g 217 °C) are processed at 350 – 370 °C while PEEK (T_m 343 °C) is processed at 370 –390 °C. Filled and high-viscosity grades may require even higher temperatures.

High temperature stability is attributable to high melting or softening points, high bond dissociation energies, structures not susceptible to chain (unzipping) degradation reactions, lack of inter- or intrabond formation, and low chemical (particularly to oxygen) reactivity. Resistance to chain degradation is perhaps the most important and is most easily provided by replac-

ing aliphatic with aromatic units. Thus although aliphatic polymers have high bond dissociation energies and the first step in degradation is a high-energy process, it yields highly reactive, free-radical species which "unzip" the chain. Unzipping is precluded in aromatic polymers because any free radicals generated are stabilized by delocalization via the π system. Furthermore, volatile fragments cannot be readily formed.

Clearly, the totally aromatic polyparaphenylene should therefore have optimum stability. It is indeed stable to above 500 °C. However, extreme chain stiffness results in an intractable material. In order to take advantage of aromatic stability but provide processibility, flexibilizing link units are incorporated into the chain [O, S, $C(CH_3)_2$]. Other, relatively inert moieties may be used to replace the aromatic ring (e.g., SO_2, CO). The balancing of these groupings gives the polymers their characteristic properties.

2. Polyetherimides

In 1982 General Electric Plastics introduced the first and still only thermally processible polyetherimide (PEI) resin under the trade name Ultem [*61128-24-3*]. It was the result of a ten-year development effort headed by J. Wirth of General Electric's Center of Research and Development in Schenectady (USA). The idea behind this development was to maintain the already known thermal and chemical stability associated with the aromatic ether and imide structures while building a polymer chain flexible enough to provide melt processability within the limits of the melt stability.

Polyimides are condensation polymers derived from bifunctional carboxylic anhydrides and primary diamines. Polyetherimides form a special class within these polyimides as they contain an ether group in either or both the aromatic dianhydride or aromatic diamine building block. A number of possible monomeric units are shown in Table 1. To date, Ultem produced from bisphenol A bisether dianhydride is the only commercially available thermoplastic polyetherimide. The synthesis thereof forms the basis for the development of these PEI resins [2, 3].

2.1. Production

Polyetherimides are synthesized by melt polycondensation of bisphenol A dianhydride with a diamine, usually *m*-phenylenediamine [4]. The starting dianhydride for PEI is produced as follows. First, an *N*-alkyl phthalimide is nitrated:

The NO_2 groups are then nucleophilically displaced by bisphenolate A (BPA) ions:

The resulting BPA diimide can be converted into the desired BPA dianhydride by an exchange reaction with phthalic anhydride:

The final polycondensation of the BPA dianhydride with an aromatic diamine (e.g., *m*-phenylenediamine) can be performed in a number of ways, ultimately resulting in the formation of PEI:

Table 1. Possible monomers in polyetherimides

Name	Structure
Dianhydrides	
Hydroquinone bis(3,4-dicarboxyphenyl)ether dianhydride	Bis(3,4-dicarboxyphenyl)ether dianhydride	Bisphenol A bis(3,4-dicarboxyphenyl)ether dianhydride	Diamines

Ultem Polyetherimide
(GE Plastics)

Kapton (Du Pont)

Figure 1. Polyetherimide (PEI) structures

PEI resins with a number-average molecular mass of 15 000 – 17 000 are usually produced. The number-average molecular mass can be adjusted with monofunctional phthalic anhydride [5, 6]. Commercial PEI grades are tuned to the specific needs of an application and are obtained in three ways:

1) Use of additives, such as reinforcing fibers, mineral fillers, conductive fibers, pigments, polytetrafluoroethylene (to reduce frictional resistance), release agents, and flow improvers.

2) Modification of the base resin by copolycondensation with other monomers such as *p*-phenylenediamine and pyromellitic anhydride. This allows for higher glass transition temperatures and/or changes in chemical resistance.
3) Blending with other polymers (e.g., polycarbonate) improves processibility and impact resistance.

Figure 2. Stress – strain curves of unmodified PEI and glass reinforced PEI
a) Unmodified PEI; b) 10 % glass-reinforced PEI; c) 20 % glass-reinforced PEI; d) 30 % glass-reinforced PEI; e) 40 % glass-reinforced PEI

2.2. Properties

The structures of Ultem and Kapton, a polyetherimide produced by Du Pont (available as "Kapton polyimide film"), are shown in Figure 1 [7–9]. The segmental mainchain rotational freedom in Ultem (shown by arrows) provides this PEI molecule with many more configurational possibilities than the more symmetrical Kapton. Ultem therefore has a lower glass transition temperature (217 °C) than Kapton (360 °C) and can be more readily melt processed. The thermal stability of both polymers is almost the same (± 500 °C under nitrogen) [10]. Properties of some Ultem grades are listed in Table 2.

Mechanical Properties. Ultem has a very high tensile strength of about 110 MPa compared to, for example, polycarbonate (60 MPa), as well as a long-term, high-load, high-temperature dimensional stability. This is the combined effect of a high glass transition temperature, a high tensile modulus, a low thermal expansion coefficient, low creep, and a low water absorption. Stress – strain behavior is shown in Figure 2.

Figure 3. Tensile strength (A) and flexural modulus (B) of nonreinforced and glass-reinforced PEI
a) Ultem 2300 (30 % glass-reinforced); b) Ultem 2200 (20 % glass-reinforced); c) Ultem 2100 (10 % glass-reinforced); d) Ultem 1000 (nonreinforced)

The relatively constant mechanical property profile of the PEI grades as a function of glass fiber content over a wide temperature range (up to 175 °C) is a direct result of the high glass transition temperature (217 °C) of this amorphous resin (Fig. 3). The excellent adhesion of PEI resins to glass fibers gives a linear relationship between the flexural modulus or tensile strength and glass fiber content up to 30 wt % [11].

Fatigue properties are excellent. The endurance (stress) limit at $10^6 - 10^8$ cycles for PEI reinforced with 30 % glass fibers is 30 MPa. Isochronous stress – strain diagrams from which

Aging characteristics (UL 94 temperature index) indicate a continuous service life up to 100 000 h at 175 °C.

Figure 5. Dependence of critical strain ε_c for crazing, cracking, and dissolution of PEI versus liquid solubility parameter δ

Impact Behavior. The unfilled resin has excellent ductility due to the large number of possible segmental rotations and the high entanglement density that results from the kinked structure of the macromolecular chain. Its rather high notch sensitivity can be overcome by making sure that parts made of PEI have wellrounded edges.

Chemical Resistance. Environmental stress crazing and cracking are typical problems of amorphous engineering plastics, including to a

Figure 6. Chemical resistance of polyetherimides
Neutral basic, acidic and/or oxidative aqueous systems have no effect with the exception of aqueous amine and ammonia which cause hydrolytic breakdown of PEI resins.

lesser extent also PEI resins. Contact and subsequent interaction between the polymer and a liquid may result in dissolution or swelling, depending on the strength of the molecular interaction forces between the polymer and the liquid molecules. These forces are characteristic for each combination of liquid and amorphous polymer and are determined by the differences in solubility parameter δ, defined as

$$\delta = \sqrt{(\text{cohesive energy}/\text{molar volume})} = \sqrt{\text{cohesive energy density}}$$

For PEI δ is 9.3 – 11.7 $(\text{cal/cm}^3)^{0.5}$ [12]. Its behavior toward contact with liquids of different solubility parameters is shown in Figure 5. If the difference between the solubility parameters of PEI and the liquid is larger than 5, i.e. $-\delta_{\text{PEI}} - \delta_{\text{liquid}} - > 5\,(\text{cal/cm}^3)^{0.5}$, then no stress cracking problems are to be expected. However, if $-\delta_{\text{PEI}} - \delta_{\text{liquid}} - < 5\,(\text{cal/cm}^3)^{0.5}$, swelling of PEI is possible and stress cracking may result from load, leading to actual strain which in time may result in crack problems. Moreover, if $\delta_{\text{PEI}} \approx \delta_{\text{liquid}}$, the polymer dissolves and the part disintegrates. The chemical resistance of PEI towards several solvents is summarized in Figure 6.

Flammability. The flammability behavior of Ultem as characterized by a high limiting oxygen index (LOI) of 47 results from the highly aromatic structure with a hydrogen/carbon molar ratio of 0.64. Selfsustained burning requires an oxygen rich atmosphere of over 45 vol %, making Ultem a selfextinguishing engineering plastic [13]. Therefore PEI resins fulfil the most severe flammability requirements stipulated by various countries for different industrial segments and part thicknesses:

1) Electrical and electronics industry: Rating V-0 at 0.64 mm wall thickness according to UL 94 Rating 5 V at 1.5 mm wall thickness according to UL 94
2) Building and construction industry: Class B-1 at 1.5 mm according to DIN 4102 (Germany) M 1 rating at 1.5 mm according to NFP 92-501 (France) Class 0 at 1.5 mm according to BS 476, parts 6 and 7 (UK)
3) Aircraft interior construction Passed FAR 25.853 at 1.5 mm (Federal Aviation Regulations, USA)

Requirements with respect to heat, smoke, and toxic gas generation during burning can also be met. Both the heat release rate criterion of ≤ 65 W at a 65 W radiation energy input and the NBS smoke density criteria (measured according to ASTM D 662) can easily be complied with.

Electrical properties of unfilled PEI and PEI reinforced with 30 % glass fiber are presented in Table 3. The dielectric constant ε has a nearly constant value over the entire service temperature and frequency range. The temperature and frequency dependence of the dissipation factor (Fig. 7) are much lower for PEI than for other engineering resins. The values at 915 and 2450 MHz are of particular interest since these are the most well-developed microwave bands for power applications. The low value (in an absolute sense) ensures that dielectric losses are minimal, especially at high temperatures.

Table 3. Electrical properties of PEI

Property	Test	Unfilled	30 % reinforced with glass fiber
Dielectric strength, V/mm	D 149	2840	2520

a) 23 °C; b) 49 °C; c) 82 °C

Weather and radiation resistance of PEI parts is excellent. A 1000-h weatherometer test had no effect on mechanical properties.

2.3. Processing

The rheological characteristics of PEI resins allow them to be subjected to all thermoplastic processing techniques, i.e., injection (blow) molding, extrusion, structural foam molding, and compression molding [14]. Processing should be based on guidelines applicable to amorphous engineering plastics, but with appropriate temperature adjustments. The high glass transition temperature (217 °C) requires a melt temperature typically in the range 360 – 425 °C. Clean, well-processed regrind can be recycled in the feed in amounts of 20 – 50 %. PEI resins absorb water and have to be extensively predried before they are melt processed to prevent severe surface splay upon molding or extrusion. Heating for at least 4 h at 150 °C is required to lower the water content to the desired level of 0.03 %.

Although processing fumes are negligible, proper ventilation is advised. Purging of the processing equipment can be achieved with high molecular mass polyethylene in combination with a gradual lowering of the melt temperature from 400 to 200 °C.

2.4. Uses

Commercial PEI grades are used in several industrial segments, of which the most important are reviewed below [15].

The *automotive industry* uses PEI mainly in under-the-hood applications, where long-term mechanical strength and dimensional stability are required at high service temperatures in combination with resistance to oil, grease, brake- and cooling fluids. Examples are sensor housings, oil pump parts, ball bearing cages, and bearings.

PEI can easily be metallized and is therefore used in head-lamp reflectors, especially in combination with energy-intensive halogen lamps.

The *lighting industry* has similar requirements to those mentioned above for head-lamp reflectors. A special feature of PEI is its IR transparency. Thus unfilled, unpigmented PEI reflectors made by dichroic layer technology can produce "cool" light. Heat is not concentrated by the reflector but diffuses through it. This principle is of importance in lighting systems employed in operating theaters, art exhibitions, etc. The dichroic coating technique uses the different refraction of various wavelengths at interfaces and its dependence on layer thickness to separate the IR and the visible part of the emitted light. The visible part of the spectrum is reflected, whereas the IR part diffuses through the PEI.

The *electrical and electronic industries* make use of PEI's intrinsic flame resistance and its excellent dielectric properties. Notable is the development of two- and three-dimensional injection-molded, printed circuit board structures where the design allows integration of mechanical and circuitry functionality. A special, newly developed, metal-plating technique for PEI makes this even more interesting

[16]. Other applications include circuit boards, connectors, switches, and controls. PEI's low tracking resistance (comparative tracking index=145 V, according to IEC standards) makes it unsuitable for high-voltage parts that carry direct current.

Polyetherimides are also used in the *food processing and beverage industries* on account of their high heat resistance, favorable mechanical properties, good chemical resistance to and cleanability (sterilization) of contact liquids, as well as lack of toxicity and disadvantageous effects in taste and odor. Specially developed PEI grades fulfil these requirements and have been formally approved by most European health agencies (e.g., Bundesgesundheitsamt in Germany) and the FDA in the United States. Polyetherimides are used in liquid-handling equipment, pumps, high-pressure dispensors, coffee makers, kitchen utensils, microwave trays, dishes and cups, cheese molds, and lightweight unbreakable baking forms. The food processing industry is becoming one of the most important volume markets for PEI.

PEI parts are also utilized in *household appliances*, e.g., water reservoirs for steam irons, hair dryers, doors of microwave ovens, and coffeemaker reservoirs.

Medical equipment often has to be sterilized and must be inert to body fluids. Here, parts made of PEI have a good performance and can be sterilized by all conventional methods (e.g., use of steam, irradiation, and chemicals). The intrinsic transparency of the material is also advantageous. Examples of applications in the medical equipment sector include surgical staplers and sterilization tanks.

The *aircraft industry* is also interested in materials that offer cost and weight savings without sacrificing safety (especially in relation to flammability issues). Components made of PEI with a high volume fraction of glass fibers or other high modulus fiber provide an excellent substitute for metal (especially aluminum) parts. The injection moldability of PEI resins allows the economic production of complex parts and multifunctional integration. High-performance composite sheets with PEI as the binding resin are used in monolithic and laminated structural parts, such as interior partition walls and floor elements. Ducts and casings are also made from PEI composites. The composites have a thermoplastic matrix and can easily be thermoformed into complex shapes.

2.5. Economic Aspects

The commercial development of PEI has been very successful. Since the introduction of the first commercial Ultem grade in 1982, annual worldwide sales volume exceeded 5000 t in 1990. Future growth is expected to increase because applications are expanding and further market development activities are underway. Potential large-volume markets in composites and in household and industrial appliances are emerging. Extra market growth may be expected from developments in high-speed trains, where the same composite materials can be used as in the aircraft industry due to the emphasis on fire safety issues. Possible markets for the compatible PEI – polycarbonate blends and the completely miscible PEI – polyetherketone or PEI – polyetheretherketone blends have not yet been fully exploited [17]. Moreover, the product range of these materials will be further enlarged by simple modification of the PEI structure through copolymerization, leading to enhanced inherent properties. An example of the flexibility offered by chemical modification of the polymer main chain is siloxane – etherimide block copolymers (PSEI) [18]. Siloxane segments provide not only flexibility, toughness, and reduced moisture absorption, but also specific surface properties and lower dielectric constant. The length of the siloxane blocks is the key to these properties [18]. PSEI copolymers have been commercialized by GE Plastics under the trade name Siltem as high-performance coating materials for electrical wires. They are also used with Ultem in aircraft interior applications where they improved the impact performance of PEI, while maintaining its flame retardancy and heat resistance. Applications of PEI do not pose any environmental issues. It is possible to recycle PEI, provided the material has been well processed and does not contain impurities.

3. Polyaryletherketones

The first reports of syntheses of polyaryletherketones appeared in the early 1960s [19, 20]

and were based on electrophilic substitution reactions, essentially Friedel–Crafts acylations. The problem of limited solubility of the crystalline polymers was solved by conducting polymerization in strongly acidic media, initially polyphosphoric acid [21] and later HF/BF_3 [22], which dissolved the polymers by protonation of their carbonyl groups. Despite the fact that high molecular mass polymers with useful mechanical properties could be produced, production problems associated with the highly aggressive reaction medium and problems in obtaining pure, stable polymers retarded the full commercialization of polyaryletherketones.

Poly(oxy-1,4-phenylenecarbonyl-1,4-phenylene) [*27380-27-4*] (polyetherketone, PEK), synthesized by polyacylation in HF/BF_3, was available on a limited scale from Raychem for a short period in the mid 1970s as "Stilan".

Polyetherketone PEK

The first synthesis of polyaryletherketones by nucleophilic displacement was reported by Johnson et al. [23] (Union Carbide) in the late 1960s, but the molecular masses of the polymers were low due to crystallization resulting in premature precipitation; mechanical properties were consequently poor.

The key breakthrough in the synthesis of polyaryletherketones by nucleophilic displacement was the identification by Rose et al. [24,25] (ICI) of diphenyl sulfone as a suitable solvent for the potentially highly crystalline, high molecular mass polymers. Nucleophilic displacement polymerization in this solvent formed the basis of the large scale industrial route to poly(oxy-1,4-phenyleneoxy-1,4-phenylenecarbonyl-1,4-phenylene) [*31694-16-3*]

(polyetheretherketone, PEEK), the first polyaryletherketone to be fully commercialized. PEEK has been commercially available from ICI since the early 1980s and PEK, synthesized by a similar nucleophilic route, since 1987.

Polyetheretherketone PEEK

The major producer of polyaryletherketone resins is ICI (Victrex PEEK and PEK). Several other companies have introduced polyaryletherketone resins (Du Pont with PEKK, Amoco with Kadel, Hoechst with Hostatec, and BASF with Ultrapek).

3.1. Production

PEEK. The most commercially significant polyaryletherketone, PEEK, is prepared by reacting 1,4-benzenediol with 4,4′-difluorobenzophenone in diphenyl sulfone in the presence of alkali-metal carbonates under an inert atmosphere at temperatures approaching the melting point of the polymer (> 300 °C) [26]. The polymer is isolated from the diphenyl sulfone and inorganic impurities, which can destabilize the polymer melt, by solvent extraction (leaching). A slight excess of 4,4′-difluorobenzophenone is normally employed to prevent the formation of phenoxide chain ends which can destabilize the polymer. The water formed as a result of polycondensation could potentially hydrolyze the fluoro groups and prevent formation of high molecular mass polymer but is lost due to the high reaction temperature and the hydrophobicity of solvent. The expensive difluoro monomer is required rather than the less expensive dichloro analogue because the weakly electron-withdrawing carbonyl group does not strongly activate the halogen to nucleophilic displacement and consequently a good leaving group is necessary for efficient reaction.

PEK is produced by ICI by two nucleophilic routes [25] which are essentially similar to the route to PEEK. The two-monomer route employs 4,4′-dihydroxybenzophenone in place of 1,4-benzenediol. The single-monomer route employs the potassium salt of 4-fluoro-4′-hydroxybenzophenone. The latter route has the greatest tendency to exhibit side reactions leading to branching (via carbanion formation due to abstraction of a proton ortho to the fluoro group of the monomer) which results in polymers with inferior mechanical properties. The two-monomer route is therefore usually preferred.

PEK has been produced by electrophilic acylation [27]. The most convenient synthe-

sis involves the Friedel – Crafts polycondensation of 4-phenoxybenzoyl chloride. The preferred reaction medium of HF/BF_3 necessitates the use of special polytetrafluoroethylene reaction vessels. This electrophilic route employs relatively cheap nonfluoro-substituted aromatic monomers. If the problems associated with the aggressive reaction medium can be solved, this may prove to be the cheapest source of PEK.

3.2. Properties

The similar structures of polyaryletherketones result in polymers with similar properties and are mainly exemplified with data for PEEK (Table 4).

Table 4. Properties of PEEK

Property *	PEEK 450 P	30 % glass reinforced

Notched	83	96

* Appropriate ASTM test methods are given in parentheses.

Physicochemical Properties. Most wholly aromatic polyaryletherketones are semicrystalline due to the strong interchain forces between the polar groups in the backbone and the crystallographic near equivalence of the ether and carbonyl units [28]. Many of the desirable properties of commercial polyaryletherketones are related to the tendency to develop a high degree of crystallinity under normal processing conditions.

The semicrystalline morphology of polyaryletherketones is largely responsible for their excellent resistance to solvent attack. PEEK is insoluble in all common solvents. It is soluble at room temperature only in strongly acidic media (e.g., concentrated sulfuric acid, hydrofluoric acid, and trifluoromethanesulfonic acid) that can protonate the carbonyl groups. At temperatures well above the glass transition temperature the polymer is soluble in a few unusual media (e.g., diphenyl sulfone, some high boiling point esters, benzophenone, and 1-chloronaphthalene). PEEK absorbs small amounts of water [29] but can absorb significant amounts of dichloromethane and related solvents that contain a hydrogen atom activated by neighboring electronegative groups [29, 30].

The insolubility of polyaryletherketones causes problems in the molecular mass characterization of the polymers. Viscometry and light scattering methods using concentrated sulfuric acid and a high-temperature gel permeation chromatography method have been developed [31]. The number-average molecular mass of commercial PEEK grades is typically of the order of tens of thousands.

The essentially linear aromatic backbone of PEEK results in excellent resistance to chemical attack and ionizing radiation. The only common reagents that degrade PEEK are chlorine, bromine, and concentrated nitric acid [32]. Dissolution of polyaryletherketones in concentrated sulfuric acid results in monosulfonation of the aromatic rings substituted by two ether linkages [33].

PEEK displays limited resistance to degradation by UV light, as is the case for all linear polyaromatics, but the problem is only serious in high insolation environments (i.e., prolonged exposure to intense sunlight) and is much reduced by incorporation of a suitable pigment (e.g., carbon black).

Thermal Properties. Differential scanning calorimetry studies of quenched amorphous PEEK indicate a T_g at 143 °C, a crystallization exotherm centered at 180 °C, and a melting endotherm with a maximum at 334 °C [34]. Increasing the ratio of carbonyl to ether linkages in polyarylether backbones increases the T_g and the melting point, PEK therefore has a T_g at 160 °C and T_m at 365 °C.

Isothermal crystallization studies indicate that PEEK crystallizes very rapidly [34] and normal processing conditions generally result in degrees of crystallinity of 25 – 35 %.

The thermal stability of polyaryletherketones is excellent. PEEK melts are stable for > 1 h at 400 °C. Thermoxidative stability is lower with prolonged heating above 300 °C resulting in cross-linking. The presence of copper impurities

significantly accelerates the thermal degradation of PEEK melts [35].

Mechanical Properties. The high crystallinity rapidly developed by PEEK and PEK results in very high flexural modulus and tensile strength. These properties decrease substantially above the T_g but useful residual values are maintained to over 250 °C, close to the melting of the crystalline regions and the maximum service temperature of the polymers reflects this. The higher T_g and T_m of PEK result in improved high-temperature retention of properties.

PEEK compositions containing glass or carbon fibers have improved mechanical properties and high-temperature performance.

Commercial polyaryletherketones are hard and display excellent wear and abrasion resistance. They are notch-sensitive like many thermoplastics, i.e., the presence of a stress-raising feature lowers the otherwise acceptable impact strength.

Electrical Properties. PEEK has a high volume resistivity (i.e., is a good insulator) and a low dissipation factor for electromagnetic radiation. Furthermore these are stable over a wide temperature range up to the T_g.

3.3. Processing

The thermal stability of commercial polyaryletherketones allows melt processing in conventional equipment [36]. This, coupled with the ability to recycle scrap material, represents a major advantage over thermosets with otherwise comparable performance.

Articles are readily prepared by injection or compression molding. Many other common fabrication techniques, notably thermoforming, centrifugal casting, and machining, are also possible. Extrusion techniques can be used to make amorphous or crystalline film and monofilament or multifilament fibers.

3.4. Uses

The uses of polyaryletherketones are generally connected with their outstanding high-temperature performance and chemical resistance.

PEEK and PEK have been widely used for cable insulation in environments where a combination of chemical resistance, high-temperature performance, abrasion resistance, and radiation resistance is required (e.g., in oil wells, nuclear installations, or aerospace applications).

In general load-bearing applications the polyaryletherketones replace metal where weight saving is critical (aerospace applications) or where the cost of the finished article is lower than the metal equivalent (recycling of scrap material combined with lower energy costs during processing).

Excellent hydrolysis and chemical resistances have resulted in PEEK replacing metal in many fluid-handling applications. Low wear rate and high abrasion resistance favor PEEK for bearing applications in aggressive environments.

PEEK film (ICI Stabar film) has been used as a barrier material and as a substrate for flexible printed circuit boards to be used at high temperature. PEEK monofilament has been woven to produce temperature- and chemical-resistant filters and transmission belting. PEEK fibers are described elsewhere, see → High-Performance Fibers, Chap. 2.3.2.

An important end use of polyaryletherketone resins is in the production of a carbon fiber composite (ICI Advanced Polymer Composite, APC) [37] which is used widely in aerospace applications due to a high strength to weight ratio coupled with resistance to aggressive service environments.

4. Polysulfones

Polysulfone is the generic term for all sulfone-containing polymers. Polysulfones are an important class of engineering thermoplastics. The polymer backbone consists of *para*-linked aromatic groups connected by ether, sulfone, and in some cases alkyl groups.

Development work on polysulfones was active by the early 1960s. Early syntheses were electrophilic, being in effect polysulfonylations [38]. This type of reaction did not generally produce a linear *para*-linked chain, and the introduction of *ortho* linkages and branchpoints resulted in polymers with poor mechanical properties [39].

An alternative strategy for the synthesis of polysulfones based on nucleophilic aromatic substitution reactions [40, 41] proved more successful for the production of *para*-linked, essentially linear polymers with good mechanical and thermal properties. This route was subsequently employed in all large-scale commercial routes to polysulfones. By the late 1960s the first commercial polysulfone, poly(oxy-1,4-phenylenesulfonyl-1,4-phenyleneoxy-1,4-phenylene(1-methylethylidene)-1,4-phenylene) or bisphenol A polysulfone [*25135-51-7*]

(Udel, Union Carbide) was available.

Udel

This was followed by the introduction in the early 1970s of the polyethersulfone poly(oxy-1,4-phenylenesulfonyl-1,4-phenylene) [*25667-42-9*]

(Victrex, PES) by ICI and Astrel 360 by 3 M, a biphenyl containing polysulfone with a high glass transition temperature but poor processability.

Victrex PES

More recent developments include the introduction of polysulfones containing biphenyl groups in the repeat unit (Radel R polyphenylsulfone [*68518-59-2*], Union Carbide; Victrex HTA [*121763-41-5*], ICI) which have higher T_g values but retain melt processibility.

Radel R

HTA

The major manufacturers of polysulfone resins are Amoco, which acquired the Union Carbide polysulfone business

(Udel, Radel A and R), and ICI (Victrex PES and Victrex HTA). BASF marketed comparable polysulfones to the ICI and Amoco polymers but on a smaller scale (Ultrason S Polysulfone, Ultrason E Polyethersulfone).

Since drafts were first submitted for publication, ICI has announced that it is to withdraw from the manufacture and sale of Victrex PES and HTA. BASF have announced a capacity increase for their Ultrason products.

4.1. Production

Bisphenol A polysulfone (Udel) is synthesized by nucleophilic substitution of 4,4′-dichlorodiphenyl sulfone (DCDPS) by 4,4′-(1-methylethylidene)bisphenol (bisphenol A) in a dipolar aprotic solvent such as dimethyl sulfoxide (DMSO) [42]. The reaction is carried out in two stages. Firstly addition of two equivalents of aqueous NaOH or KOH to a solution of the bisphenol in a mixture of DMSO and azeotroping solvent (e.g., chlorobenzene) generates the more nucleophilic bisphenate salt. Excess water is then removed by azeotropic distillation at 120 – 140 °C before the dichloro monomer, which could be hydrolyzed by water and lead to a low molecular mass product, is added and polymerization proceeds. Polymerization is carried out at 130 – 160 °C under an inert atmosphere to prevent oxidation of the bisphenate salt. The dipolar aprotic solvent promotes very rapid rates of nucleophilic substitution and the molecular mass of the polymer can become excessively high unless it is controlled by the addition of monofunctional halides or phenols.

Radel R and Radel A (structure not disclosed) are probably also synthesized by this type of

route but employing the appropriate bisphenol monomers.

The synthesis of Victrex PES is similar to the synthetic route to Udel with 4,4′-sulfonylbisphenol (bisphenol S) being condensed with DCDPS [43]. The lower solubility and reactivity of the bisphenol (nucleophilicity reduced by electron-withdrawing sulfone group para to the hydroxy group) necessitates a significantly higher reaction temperature (up to 285 °C). Consequently, the dipolar aprotic solvent used is diphenyl sulfone, phenate salts being notionally generated "in situ" by the action of K_2CO_3 or Na_2CO_3. The high reaction temperature and the hydrophobicity of the solvent result in the efficient removal of water that might otherwise hydrolyze the dichloro monomer. Azeotropic distillation is not necessary.

Victrex HTA is produced by an analogous route but with the DCDPS being replaced by bis(4-chlorophenylsulfonyl)biphenyl.

4.2. Properties

Physicochemical Properties. Key properties of Udel polysulfone and Victrex PES are listed in Table 5.

Table 5. Properties of Udel polysulfone and PES

Properties ∗	Udel polysulfone P 1700	Victrex PES 4100 G

Izod impact strength, J/m (D 256)		
Unnotched	no break	no break
Notched	69	83

∗ Appropriate ASTM test method given in parentheses.

All commercial polysulfones are essentially amorphous as utilized. The unfilled polymers display good clarity.

The polysulfones are relatively polar and their solubility characteristics reflect this. Polysulfones are soluble to some extent in a variety of dipolar aprotic solvents (e.g., dimethyl sulfoxide, dimethylformamide, *N*-methylpyrrolidone) and certain chlorinated hydrocarbons (e.g., dichloromethane, chlorobenzene). Udel polysulfone is significantly soluble in low molecular mass ketones and some aromatic hydrocarbons [44]. Victrex PES and biphenyl-containing polysulfones are more solvent resistant than Udel polysulfone [45]. The polysulfones are crazed but not dissolved by solvents with polarities similar to that of the polymer and this tendency increases with stressed samples.

Polysulfones can absorb small amounts of water but this has a minimal adverse effect on dimensions and mechanical properties. Polysulfones are very resistant to hydrolysis, even by hot water or steam. They are stable to dilute acid and caustic but are degraded by concentrated nitric and sulfuric acids. Chlorine and bromine also degrade polysulfones.

Polysulfones show limited stability to UV light and the materials must be filled for outdoor applications. Resistance of the wholly aromatic polysulfones to ionizing radiation is excellent, Udel polysulfone has a lower resistance due to the presence of aliphatic groups.

The ready solubility of polysulfones allows the determination of average molecular masses and distributions by a variety of common techniques including gel permeation chromatography. Number-average molecular masses of commercial polysulfones are typically of the order of tens of thousands.

Thermal Properties. Commercial polysulfones cannot be crystallized from the melt or by annealing and are amorphous as utilized. The T_g tends therefore to be responsible for short-term temperature ceilings (e.g., heat deflection temperature) for applications of the polymers. Aromatic rings and sulfone groups introduce chain rigidity whereas ether links increase flexibility. Hence increasing the ratio of sulfone to ether links in the repeat unit increases the T_g. The presence of biphenyl groups (e.g., HTA and Radel R) also increases chain rigidity and hence T_g.

The thermal stability of polysulfones is excellent due to the strong bonds in the backbone and results in stable melts during processing below 400 °C. The aliphatic isopropylidene groups in Udel polysulfone significantly reduce the thermooxidative stability relative to the wholly aromatic polysulfones and prevent prolonged high-temperature use close to T_g. Melt processing

on conventional equipment is still possible however.

Commercial polysulfones possess selfextinguishing behavior. Despite the presence of sulfur-containing groups, they exhibit relatively low levels of smoke and toxic gas emission.

Mechanical Properties. The polar groups in the polysulfone chain result in a very high flexural modulus. Modulus decreases rapidly as T_g is approached. The impact strength of the unnotched polymers is also high, but the presence of molded or accidental notches dramatically reduces the impact strength. The notched impact strength of the biphenyl-containing polysulfones is significantly higher than that of other polysulfones.

Filling of the polymers with glass or carbon fiber substantially increases the modulus of the polysulfones but generally only increases the heat deflection temperature slightly.

Electrical Properties. The polysulfones have high resistivities and low dielectric constants and dissipation factors for electromagnetic radiation which are substantially retained up to the T_g of the polymer.

4.3. Processing [44,46]

Commercial polysulfones are all melt processible on conventional equipment, the required processing temperatures increasing with the T_g of the polymer. The polysulfones are dried before processing to prevent the evolution of adsorbed moisture from lowering the quality of moldings. Annealing at a temperature close to the T_g of the polymer is recommended to prevent stress cracking of moldings.

4.4. Uses

The mechanical properties of Udel polysulfone and Victrex PES are similar. If enhanced high-temperature performance or chemical resistance is required Victrex PES is preferred. The biphenyl-containing polysulfones are significantly more expensive than Udel and Victrex PES, their use is limited to situations where extreme heat or impact resistance is required. Their use as films and foamed plastics are described elsewhere, see → Films, Chap. 6.10., → Films, Chap. 6.11.,→ Films, Chap. 6.12.,→ Films, Chap. 6.13. and → Foamed Plastics.

Udel and Victrex PES have been widely used to produce injection-molded articles, replacing metals in low- to medium-temperature applications where weight saving is important – particularly aerospace applications. Notch sensitivity limits the application of the polymers in critical load-bearing components.

The high-temperature hydrolytic stability of polysulfones has permitted widespread use in fluid-handling components and steam-sterilizable biomedical moldings. Chemical resistance enables a range of chemical process and automotive applications.

Good insulating properties up to high temperatures favor polysulfones as insulation for electrical cables and as a circuit board material (→ Insulation, Electric, → Insulation, Electric).

5. Poly(Phenylene Sulfide)

Poly(phenylene sulfide) [*9016-75-5*] (PPS), poly(thio-1,4-phenylene), is the most important thermoplastically processible representative of the poly(arylene sulfides). The latter consist of repeating aromatic monomer units joined by sulfur bridges:

On account of its unusual properties, PPS is expected to experience an above-average increase in production and sales [47].

PPS was first obtained in 1888 as a polymeric byproduct by Friedel and Crafts [48,49]. Attempts by Genvresse (1897) to prepare PPS from benzene and sulfur with aluminum chloride resulted in cross-linked resins and a large number of low molecular mass byproducts [50, 51]. In the late 1940s Macallum developed a process for preparing poly(arylene sulfides) (including PPS). By reacting dichlorinated aromatics with sulfur, he obtained partially cross-linked products with higher sulfur contents than those predicted by their theoretical structure[52,53].

A series of publications describe the synthesis of alternating sequences of aromatic units by reacting dithiolates with dihalogenated compounds [54–57] and the first use of polar aprotic solvents [54].

In the early 1960s a process was developed by Dow which involved copper-induced self-condensation of aromatic halothiophenols and resulted in an experimental product [51,58,59].

In 1963 Edmonds and Hill developed a new process in which poly(arylene sulfides) were prepared from dihalogenated aromatics with sodium sulfide in a suitable polar aprotic solvent [60]. Since 1972 PPS has been produced on an industrial scale according to this method by Phillips Petroleum and marketed under the name Ryton. Other industrial methods are all based on this principle:

Some new synthetic pathways for producing PPS have been published, but have not yet resulted in industrial processes [61].

5.1. Production

The formation reaction of poly(arylene sulfides) is generally described as nucleophilic substitution of an aromatic compound, with elimination of alkali chloride.

Although the reaction appears to be extremely simple, it is a complex system of partial reactions. Synthesis is difficult to control due to extreme differences in reactivity in the course of the polycondensation [62]. Secondary reactions (in some cases radical-induced) lead to functionality losses, as well as production of undesirable byproducts and cyclic oligomers [63]. Industrial production is possible only if all the reaction parameters are strictly defined and controlled.

In the first process developed by Phillips Petroleum (see Section 5) sodium sulfide hydrate is dissolved in *N*-methylpyrrolidone. In a development of this process the sulfur component is incorporated in a two-stage reaction. In the first stage sodium hydroxide is reacted with the solvent *N*-methylpyrrolidone and in the second stage hydrogen sulfide gas is introduced [64]. Some of the water can be removed by distillation before adding 1,4-dichlorobenzene. The reaction is brought to completion under increasing pressure at temperatures up to 290 °C [60]. Modifications of this process include metering [65], specific temperature controls [66], and continuous mode of operation [67].

The reaction product is a suspension that contains PPS and sodium chloride as the solid phase. The suspension can be freed from volatile substances such as water, *N*-methylpyrrolidone, and dichlorobenzene by, for example, flash evaporation [68]. The resulting powder consists of polymer and salt. It is washed with water at various pressures and temperatures to remove the salt and then dried [69].

The procedure described above only produce low molecular mass PPS which is unsuitable for further processing (e.g., by extrusion or injection molding). In order to achieve the necessary molecular mass, the PPS powder is cured. The melt flow index (MFI) can be reduced from about 6000 g/10 min to 50–700 g/10 min (ASTM D 1238-70, 316 °C, 5 kg) by chain extension and branching after thermooxidation with an oxidizing agent (in the simplest form with air) [70].

Higher molecular mass PPS can be obtained by using catalysts (e.g., sodium or lithium acetate) and possibly branching agents (trifunctional halogenated aromatics) [71], and by establishing a defined water content [72].

The high molecular mass PPS forms a separate molten phase, up to 15 % of the total PPS remains as a low molecular mass fraction in the solvent phase. This latter fraction has to be separated by screening [73].

In a further development of this process, instead of using catalysts water is selectively added to the low molecular mass PPS solution which then undergoes complete phase separation and further condensation in the separated liquid phase. High molecular mass, linear polymers can thus be obtained [74].

In another variant, high molecular mass PPS is produced directly in a solvent (e.g., *N*-methylcaprolactam), in the absence of water. Any water contained in the reactants is subsequently removed by azeotropic distillation with the dihalogenated aromatic reactant. In this way the reaction can be brought to completion in a very controlled manner under simple reflux dis-

tillation. This procedure can be carried out as a continuous process [75].

The use of special catalysts (e.g., amino acids) and new workup methods result in a further improvement in product properties [76].

5.2. Properties

5.2.1. Material Properties

The properties of PPS may vary to a limited extent, depending on the production process and workup.

Various methods have been described for characterizing the melt behavior and estimating the molecular mass of PPS. A commonly employed method is the measurement of a melt index:

(melt flow index (MFI) in g/10 min, or melt volume index (MVI) in mL/10 min). In many publications the ASTM D 1238-70 standard with a modified application force (5 kg) and melt temperature (316 °C) is recommended [70–72]. The method determines only one parameter, however, as a single-point measurement on a shear-dependent melt curve. Furthermore, the standard does not permit measurement of higher values (i.e., high flowability). Measurement of the melt viscosity as a function of the shear force in a cone – plate or capillary viscosimeter is more useful [77].

Solution viscosity and light scattering measurements in combination with size-exclusion chromatography (gel permeation chromatography) have also been used to determine molecular masses [78]. Industrially produced poly(arylene sulfides) generally have broad distribution curves, which become wider after curing (see above). For further details of measurement of molecular mass, see → Plastics, Analysis.

PPS can be characterized by IR or nuclear magnetic resonance spectroscopy [79]. The thermal degradation of PPS has been investigated by direct pyrolysis in the ionization source with the aid of mass spectroscopy. In the presence of oxygen, aromatic ether bonds are formed by oxidation, and condensed aromatic compounds are produced by elimination of hydrogen sulfide. Sulfur dioxide is another inorganic gaseous product [80].

Surface oxidation produces sulfoxide and sulfone groups that can be detected by electron spectroscopy for chemical analysis (ESCA) methods [81]. Thermogravimetric measurements have shown that the high thermal stability of PPS compared to other plastics is due to cross-linking reactions [82].

Chloroaryl, thiol, or thiolate groups may be expected as end groups for poly(arylene sulfides) with a regular structure. The chlorine end group content can be determined by elemental trace analysis (e.g., Wickbold combustion) [83]. Determination of thiol groups is more difficult, a wet chemical method is described in [84].

The content of ionic impurities may be critical in certain applications, for example in the electronics sector. The polymer must be brought into solution to release and determine its salt content [85]. A physical method for determining chloride ions has also been published [86].

5.2.2. Properties of Nonreinforced Moldings

PPS is a partially crystalline material. Moldings thus consist of an amorphous phase and a crystalline phase. The amorphous phase has a glass transition temperature of 90 °C. The thermodynamic melting point of the crystalline phase for "ideal" crystals is between 300 and 310 °C [87]. The platelet-shaped, orthorhombic crystals (length and width $\leq$ 1000 nm, thickness $\leq$ 10 nm) in moldings have a melting point between 280 and 285 °C. The PPS crystallites form spherical spherulites from still melts, and stacks with a hard-fiber morphology from flowing melts [88].

During injection molding or extrusion, PPS crystallizes when the melt is cooled. Differential scanning calorimetry (DSC) shows that crystallization begins at about 250 °C. The final degree of crystallinity depends on whether the melt is cooled above or below the crystallization temperature of ca. 127 °C, and how quickly this takes place.

It is often impossible to obtain the maximum degree of crystallization during injection molding. Such moldings may become distorted due to post-shrinkage during subsequent use under thermal stress. In order to ensure that PPS moldings are dimensionally stable during subsequent use, it may therefore be necessary to

Table 6. Mechanical properties of nonreinforced PPS

temper them beforehand (i.e., to store them at elevated temperature, e.g., 220 °C) to complete their crystallization under controlled conditions.

Injection moldings of nonreinforced PPS have high tensile and flexural strengths, as well as high moduli of elasticity (Table 6). They have a high rigidity and a low flexibility, with the result that they may fracture even under very small loads. The impact strength and notched impact strength are also extremely low. Whereas moldings of low-viscosity PPS exhibit brittle fracture even under slight deformation, moldings of high-viscosity PPS can be deformed before they fracture in a ductile manner [89].

at 1 MHz		0.0009

Thermal and electrical properties of nonreinforced PPS are listed in Table 7. Moldings of nonreinforced PPS that are not mechanically stressed retain their shape up to the melting temperature. Under mechanical loads, however, they become deformed above ca. 90 °C, i.e., the glass transition temperature. For a partially crystalline thermoplastic the coefficient of linear thermal expansion is extremely low. The thermal conductivity of PPS is also very low [90].

On the basis of its dielectric values and resistance values PPS is a slightly polar insulator.

PPS is an inherently flame-resistant thermoplastics (oxygen index 0.44). It is classified as a V-0 material (UL 94) at a thickness of 0.8 mm (→ Flame Retardants, Chap. 3.) [90].

At low temperature PPS is resistant to all organic solvents and chemicals. PPS moldings swell, however, under the action of some organic compounds on heating, particularly after prolonged exposure (Table 8). PPS is extremely resistant to acids and alkalis but oxidizing agents, in particular nitric acid, attack PPS on heating and destroy the moldings. PPS is moderately permeable to diffusion of gases and water vapor [91].

Table 8. Chemical resistance of PPS on storage at 93 °C

5.2.3. Properties of Reinforced Moldings

Reinforcement of PPS with fibers and/or mineral fillers increases its mechanical strength and thereby compensates for its low impact strength,

and also improves its dimensional stability at high temperature. Fibrous reinforcing materials are usually made of glass but carbon fibers and aramid fibers are also employed on a small scale. Mineral fillers are generally used in combination with glass fibers and include calcium carbonate, kaolin, calcium sulfate, mica, talc, and quartz. These fillers and reinforcing materials can be incorporated into PPS in high concentrations (up to about 70 wt %) by using conventional compounding equipment [91–94].

Injection moldings made of glass-fiber-reinforced PPS have a high hardness, ultimate tensile strength, flexural strength, and modulus of elasticity, but a very low formability and ductility and only moderate impact strength and notched impact strength. Such moldings can permanently withstand high vibrational stress. The slip properties and abrasion resistance of glass-fiber-reinforced PPS molding compounds are inferior to those of other partially crystalline thermoplastics reinforced with glass fibers [93].

Glass fiber – mineral-reinforced PPS injection molding compounds have relatively high hardness and rigidity, and relatively low impact strength and percentage elongation at break (Table 9). The properties may be altered within wide limits by varying the weight ratio of glass fibers to mineral fillers [91, 92].

Reinforcing PPS with mineral fillers also considerably improves its heat resistance, hardness, and rigidity (Table 10). It also results in moldings with very smooth surfaces and high dimensional stability. Omission of fibrous reinforcement means, however, that the flexural and tensile strengths of the moldings are very low: they can be deformed only very slightly before they fracture [91, 92].

Nonreinforced PPS exhibits partial softening at 90 °C and moldings cannot be mechanically stressed above this temperature. Reinforcement with glass fibers or minerals improves the strength to such an extent that moldings can withstand mechanical stress at elevated temperature. This is reflected in the heat resistance values according to ISO 75, i.e., the heat deflection temperature (HDT), which consistently lies between 260 and 270 °C [91, 92].

Maximum service temperature is characterized by relative temperature indices which are the temperatures at which 50 % loss of initial mechanical properties occurs after an exposure of 25 000 h. The relative temperature indices of reinforced and filled PPS molding materials are 200 – 240 °C. The thermal conductivity of reinforced PPS injection molding compounds is primarily determined by their glass fiber content and the fiber orientation in the molding. In moldings fabricated from materials reinforced with glass fibers and mineral fillers, the anisotropy of the thermal expansion is less. Reinforced PPS injection molding compounds are recommended as excellent electrical insulators on account of their high volume resistivity and surface resistivity (Table 11) [91, 92].

Table 11. Electrical properties of reinforced PPS molding compounds (measurements made at Bayer)

Property	KU 1-9511	KU 1-9521
Specific volume resistance, Ω · cm (VDE 0303, part 1)		
4 d, 23 °C, 50 % R.H.	7.2×10^{15}	2.5×10^{15}

Surface resistivity, Ω · cm (VDE 0303, part 3)		
4 d, 23 °C, 50 % R.H.	6.4×10^{15}	2.7×10^{15}
4 d, 23 °C, 92 % R.H.	9.6×10^{13}	3.4×10^{13}

Reinforced PPS molding materials are extremely flame-resistant, with a very low fume density. In addition they pass the Ohio State University (OSU) test [91, 92].

Moldings are extremely resistant to most organic compounds, even at elevated temperatures. However, on prolonged storage at elevated temperature in water or in water vapor they lose up to 60 % of their initial strength [94]. Water absorption is extremely low, even in boiling water, and accordingly dimensional changes due to water absorption do not occur. Under prolonged storage in hot air, above ca. 120 °C PPS injection moldings turn brown. However, this is not associated with reduction of mechanical strength (maximum use temperature: 200 – 240 °C) [91, 92].

PPS undergoes photooxidation in the light, and prolonged weathering results in yellowing and moldings with a dull, rough surface. Their mechanical strength decreases only very slowly however. PPS is resistant to high-energy radiation [91, 92].

Repeated processing of PPS injection molding compounds does not result in degradation of the PPS macromolecules, as is confirmed by the constant melt viscosity. Recycling of regen-

erated material from sprues and defective parts is therefore acceptable [91, 92].

5.3. Processing

5.3.1. Injection Molding [95]

PPS injection molding materials containing glass fibers and/or minerals have an extremely good processibility on account of their low melt viscosity.

Injection Conditions. It has proved advantageous to store the molding powder for 3 – 6 h at ca. 150 °C prior to injection molding to remove any volatile constituents. Materials that contain hydrophilic fillers should always be dried beforehand under these conditions.

PPS injection molding compounds are processed at melt temperatures of 350 – 370 °C, the most common range is 320 – 340 °C. PPS only crystallizes extremely slowly and incompletely below 120 – 130 °C, the temperature of the molds must therefore be above 130 °C and, if possible, between 150 and 170 °C to obtain moldings with smooth, uniform surfaces.

Solidification during filling results in surface damage and weak spots on the moldings. The injection rate should therefore be as high as possible and is usually performed at 75 – 150 MPa. High injection pressures are advantageous since they ensure uniform moldings, good surfaces, and favorable mechanical properties. Overinjection can easily occur however, with the formation of mold marks. After-pressures of 50 – 70 % of the injection pressure are normally employed.

PPS molding compounds can be processed in all conventional screw-injection molding devices, triple-zone screw arrangements with compression ratios of 1 : 2 to 1 : 3 are often used. PPS materials generally contain glass fibers or mineral fillers and thus, wear down screws and cylinders, particularly in the feed section. Reinforced (armor-plated) screws and cylinders are therefore recommended, with shutoff nozzles instead of open nozzles. Heated channel nozzles may also be used.

Molds. Since the PPS melt has a low viscosity, it may penetrate between the mold parting

surfaces, and thus cause formation of burrs and marks. High clamping pressures are used to prevent this.

PPS moldings reinforced with glass fibers shrink anisotropically. Nonwarping moldings can, however, be obtained by modifying the mold shape, injection rate, mold temperature, and the temperature of the melt. Shrinkage is also lower in PPS materials that contain both mineral fillers and glass fibers. Such materials are consequently better suited to the production of nonwarping, dimensionally stable moldings.

The high content of glass fibers and fillers in most PPS injection molding compounds can lead to considerable abrasion of the molds, and wear-resistant mold steels are therefore used. Steels with Rockwell hardnesses of 59 HRC to 62 HRC are preferred.

The mold cavities should be vented sufficiently rapidly, normally through venting slits in the mold parting surfaces. The slits should not be wider than 0.01 mm to avoid the formation of burrs and marks on the moldings.

5.3.2. Other Molding Methods

PPS moldings can be produced not only by injection molding (Section 5.3.1), but also by compression or by sintering PPS powders or mixtures of PPS powders and glass fibers, fillers, and/or additives (e.g., molybdenum sulfide or polytetrafluoroethylene).

The property spectrum of PPS pressed moldings is substantially inferior to that of injection moldings. The mechanical strength of sintered parts roughly corresponds to that of pressed parts of the same composition. An advantage over compression molding is that hot (360 °C) molds do not need to be handled [96].

Low-viscosity PPS powders are used to coat metallic parts (coating from aqueous dispersions, electrostatic powder coating, fluidized-bed coating). Coatings of oxidatively cross-linked PPS are rigid, flexible, and wear-resistant, and can withstand high thermal stress over prolonged periods. The chemical resistance of PPS coatings is decisive for their use in protecting metal parts against corrosion [97].

5.3.3. Finishing of Shaped Articles

Most PPS materials contain a high concentration of glass fibers and mineral fillers. The use of hard-metal drills, milling machines, and saws to finish PPS moldings is therefore recommended.

PPS moldings can be strongly bonded to one another by ultrasonic welding, hot-plate welding, and with two-component adhesives, in particular epoxy and polyurethane adhesives.

Coatings on PPS moldings can be obtained only if a polyurethane primer is applied.

5.3.4. Extrusion

Films [98]. See also → Films, Chap. 6.12.4..

Films, particularly biaxially stretched films, constitute one of the main uses of unfilled PPS, and are mainly used in capacitors. Biaxially stretched PPS films have good mechanical properties, their outstanding property being their high thermal resistance. If ignited, they rapidly cease burning after the flame has been removed. PPS films are resistant to bases, acids, solvents, and other chemicals. However they are rapidly destroyed by concentrated sulfuric or nitric acid at room temperature.

PPS films can be coated and printed after corona or plasma pretreatment. The very low polarity of the PPS molecules accounts for the low dielectric constant and the low dielectric loss factor.

To produce biaxially stretched PPS films the filtered PPS melt is extruded at ca. 320 °C onto cooled rollers. It has also proved advantageous to remove volatile constituents by degassing the melt before the extrusion, this is achieved by releasing the pressure and applying a vacuum. The amorphous film is then stretched at 90 – 120 °C successively or simultaneously in the longitudinal and transverse directions.

Fibers [99]. See also → High-Performance Fibers, Chap. 2.3.2.

Fibers constitute the second largest area of use of unfilled PPS, and are employed particularly in the form of fabrics and nonwovens for filtering hot and/or aggressive media.

PPS fibers have a high mechanical strength, and can be used for short periods up to about 230 °C, whereby they retain 40 % of their tensile

strength at 23 °C. The longterm service temperature is 190 °C. If fabrics made from PPS are ignited, they rapidly cease burning once the source of ignition is removed.

PPS fibers have a high resistance to acids, alkalis, and most organic solvents, even at elevated temperature. Oxidizing agents attack PPS fibers however. In boiling water PPS fibers may shrink by up to 10 %.

Extrusion of the raw fibers is followed by two-stage stretching and heat setting, in which the fibers are heated under tension at 265–270 °C for 1 min to ensure satisfactory crystallization of the PPS.

5.3.5. Semifinished Products

Reinforced PPS materials are processed into continuous profiled sections, rods, pipes, etc. On account of its high resistance to heat and solvents, poly(phenylene sulfide) is also an excellent matrix for high-performance composite materials [100].

5.4. Uses

The high price of PPS injection molding materials limits their uses and applications. They are therefore mainly used where technical and economic requirements cannot be satisfied by other industrial thermoplastics.

The applications of PPS molding materials are determined by their unique combination of technical advantages, the most important being:

1) High dimensional stability even at high temperature
2) Very high rigidity and hardness
3) Very good long-term static and dynamic loadability
4) Low static and dynamic coefficients of friction
5) Extremely high resistance to almost all chemicals
6) Low flammability
7) Good processability by injection molding
8) Machinability and weldability
9) Inscribability of the moldings by printing or laser inscription

The main areas of use for PPS molding materials include the electrical/electronics, automotive, and lighting sectors. PPS moldings are also used in many other market sectors, for example in household appliances, chemical plant construction, and mechanical engineering.

In the *electronics sector*, special, highly filled PPS molding compounds with particularly low melt viscosities have to some extent replaced epoxy compositions in the housing of electronics components such as transistors, coils, and capacitors. Glass fiber-reinforced PPS is also used for integrated circuit housings (chips). Connectors (e.g., high-density connectors) made of PPS reinforced with glass fibers (and minerals) are produced on a large scale in the United States. The high mechanical strength of moldings made from glass fiber-reinforced PPS accounts for its use in components of electric motors (e.g., brush holders and wound cores).

PPS molding compounds are also being used increasingly in the *automotive sector*. For example pumps in petrol tanks are fabricated from PPS reinforced with glass fiber and minerals. In pump impellers of vacuum pumps used in steering and braking systems, the PPS moldings have to satisfy extremely stringent requirements as regards dimensional accuracy, dimensional stability, mechanical strength, dynamic longterm stress, and abrasion resistance.

In the *lighting sector* the trend towards small automobile headlamps and high light intensities means that a great deal of heat is generated in a confined space. Housings are therefore made of special, highly-filled PPS molding compounds. Caps and holders of halogen lamps are also produced from glass fiber-reinforced PPS.

PPS molding compounds are employed in *chemical plant construction* (e.g., for valves, column packings, and distillation columns). In feed pumps the danger of spark formation as a result of buildup of electrostatic charge can be excluded by using PPS molding materials whose electrical conductivity has been increased by incorporating carbon black.

On account of its resistance to chemicals, PPS is suitable for *applications involving contact with food*. Certain PPS compounds have been approved by the BGA and FDA for use as a material for kitchen utensils [101].

5.5. Economic Aspects

Despite the fact that PPS has been commercially available since the mid 1970s, it is a very "young" product. On account of its outstanding property profile it has a broad, constantly increasing range of applications. Newly developed copolymers and poly(arylene sulfides) based on dihalogenated aromatics with tailor-made property profiles are reinforcing this development [102].

PPS compounds are used in strongly expanding sectors. In parallel with growing awareness among customers, further processors are beginning to use PPS which provides a good precondition for high growth rates for PPS compounds. Average annual growth rates exceeding 11 % are expected in North America, the Far East (including Japan), and Western Europe (see Table 12) [47, 103].

Table 12. PPS turnover forecast [47]

Region	Turnover, t		Average annual
	1989	1995	growth, %
North America	5 500	10 500	11.4
Far East (including Japan)	4 000	7 700	11.5
Western Europe	2 500	4 800	11.5
Total	12 000	23 000	11.5

Trade Names. In the mid 1970s only Phillips Petroleum was represented on the market, with its Ryton types. Following the expiry of the basic patents other companies are becoming increasingly active both as regards resin production and compounding [103].

Trade names of companies with their own primary resin production include Ryton (Phillips); Tedur, Tregalon (Bayer); Fortron (Kureha); Tonen PPS (Tohpren); Susteel (Tosoh Susteel); Torelina (Toray); (Sung Yong)

Trade names of companies without their own primary resin production include Supec (General Electric, United States); Tedur (Miles, United States); OFL and OCL (LNP, United States); Fortron (Hoechst Celanese, United States, Western Europe); Craston (Ciba-Geigy, Western Europe); Primef (Solvay, Western Europe), Larton (Lati; Western Europe); DIC-PPS (Dainippon Ink, Japan); Sumicon (Sumitomo Bakelite, Japan); Nova PPS (Mitsubishi Kasei, Japan); Fortron (Polyplastics, Japan); Denka PPS (Denka, Japan); Toyobo PPS (Toyobo, Japan); PPS (Ube, Japan); Petchem Idemitsu PPS (Idemitsu, Japan).

1. Introduction

Poly(methyl methacrylate) [*9011-14-7*] (PMMA) has been produced industrially since the early 1930s. The history and development of this polymer are very closely associated with the chemist Otto Röhm [1,2]. In 1932 Röhm and his collaborator W. Bauer were the first to polymerize methyl methacrylate (MMA) into transparent sheets [3]. Almost parallel to these developments at Röhm & Haas in Germany, corresponding activities were in progress at Rohm & Haas and Du Pont in the United States and at ICI in England. A few years later the first thermoplastically processable molding compounds based on PMMA were available.

PMMA occupies an intermediate position between "commodities" and "high-tech polymers" or "engineering plastics"; its market has in the meantime developed greatly. In 1988 the MMA capacities worldwide were ca. 1.5×10^6 t/a (Western Europe 4.7×10^5 t/a, North America 5.1×10^5 t/a, Japan 3.5×10^5 t/a [4], in 1992, 1.9×10^6 t/a [5]). About 50 % of this amount is used for further processing into acrylic glass and PMMA molding compounds; the remainder being distributed among dispersions, paints, binders, adhesives, additives, etc.

PMMA is the main representative of this polymer class; polymers and copolymers of higher alkyl methacrylates are of minor economic importance.

2. Properties

The properties that make PMMA a highly-prized plastic are its good mechanical strength, its outstanding optical properties (clarity, brilliance, transparency), and its extremely good weather resistance [6]. This favorable profile can be supplemented by the surface modification of semifinished products (e.g., scratch-resistant or

antistatic coating), coloring or pigmenting, and treatment with flame retardants to open up a wide variety of potential uses for this polymer (see Chap. 5).

∗ Extruded from molding compound.

Pure PMMA is an amorphous plastic with a high surface gloss, high brilliance, and crystal-clear transparency. It is classified as a hard, rigid, but brittle material. The tensile, compressive, and flexural strengths are considered satisfactory; scratch resistance is also good and can be improved further by the use of special coatings. The most important physical properties of PMMA are summarized in Table 1; a distinction is made between cast PMMA ($M_r>10^6$) and PMMA extruded from molding compounds ($M_r<5\times10^5$). The properties listed in Table 1 were determined according to the so- called basic value table [7]; further data can be found in the CAMPUS data bank [8]. This data bank also includes information about copolymers of MMA with small proportions of acrylate esters (< 10 % methyl acrylate). Incorporation of acrylate allows the rheological properties of the thermoplastics to be varied within a wide range to satisfy the processing requirements during injection molding and extrusion.

PMMA is resistant to aliphatic hydrocarbons, nonpolar solvents, aqueous alkalis, and aqueous acids. Aromatic hydrocarbons, chlorinated hydrocarbons, esters, ketones, and other polar solvents attack PMMA, causing it to dissolve or swell. Whereas alcohols and water alone are regarded as nonsolvents, their mixtures may have a solubilizing effect (cosolvency). Detailed information on solvents and precipitating agents for PMMA can be found in [9].

Most physical properties E of polymers depend on the molecular mass. For example, the viscosity of a polymer melt increases continuously with the molecular mass. Some other properties (e.g., glass transition temperature, density, refractive index) show an asymptotic behavior, which can be described by the following equation:

$$E=E_\infty+\frac{k}{\bar{M}_n} \tag{1}$$

For sufficiently high number-average molecular masses $\bar{M}_n$, a polymer-specific limiting value E_∞ is accordingly reached (typically at ca. $\bar{M}_n>50\,000$); the constant k is influenced by the terminal groups of the polymer.

Table 2 summarizes some physical properties of the most important polymethacrylates. The values were obtained at sufficiently high molecular mass (i.e., E_∞), so that the influence of the alcohol residue of the ester group can be recognized.

The glass transition temperatures T_g decrease sharply with the length of the linear, aliphatic side chain. Whereas PMMA, the first member of this homologous series, is a hard, rather rigid material, the polymers with residues larger than n-hexyl are rubber-like. The glass transition temperature decreases up to about poly(dodecyl methacrylate). With longer linear ester residues, side-chain crystallization occurs, which masks the glass transition. Polymers with linear alkyl ester residues always have a lower glass transition temperature than the branched and alicyclic isomers. Large bulky residues considerably restrict the mobility of the polymer main chain, particularly if they are joined directly to the ester group.

When discussing the data in Table 2 it has to be borne in mind that properties of a polymer, in particular the glass transition temperature, also depend on its tacticity. If a tactic polymer is regarded as a terpolymer of isotactic, syndiotactic, and heterotactic triads, then its glass transition temperature can be described by the following linear combination.

$$T_g = x_{ii}T_{g,i} + x_{is}T_{g,h} + x_{ss}T_{g,s} \quad (2)$$

where $T_{g,i}$, $T_{g,h}$, and $T_{g,s}$ denote the glass transition temperatures of the (imaginary) polymers constructed purely from isotactic, heterotactic, or syndiotactic triads, respectively, and x_{ii}, x_{is}, and x_{ss} denote the associated mole fractions of these triads in the relevant real polymer. In the case of PMMA, the values $T_{g,i}$=42 °C, $T_{g,h}$ = 139 °C, and $T_{g,s}$ = 124 °C were determined by fitting experimental T_g values to x_{ii}, x_{is}, and x_{ss} mole fractions as obtained from NMR analysis [15]; data for other polymethacrylates can be found in the literature [14]. The mole fractions x_{ii}, x_{is}, and x_{ss} depend on the polymerization temperature and the polymerization mechanism (and are possibly influenced also by any solvent used in the polymerization). These relationships have been investigated in detail in the case of PMMA [16].

All the influences on the glass transition temperature described above have not been taken into account in Table 2. Most of the listed T_g values were measured on atactic polymers synthesized by radical polymerization. This explains to some extent the considerable differences that individual authors find in one and the same polymethacrylate. In addition to this, variations also arise due to the use of different methods of measurement of T_g (dilatometry, differential scanning calorimetry) and evaluation procedures (e.g., "midpoint" and "on-set" evaluation in differential scanning calorimetry).

The residual monomer content of the polymers represents a large source of errors in the determination of T_g; even relatively small propor-

tions can lead to considerable reduction of the glass transition temperature. Methacrylates with bulky side groups (e.g., isopropyl, *tert*-butyl, or cyclohexyl methacrylate) are especially critical because even in the case of a very sharp end polymerization they yield a product that still contains a few percent of residual monomers [17]. The values listed in Table 2 were obtained on reprecipitated, carefully dried material and are considerably higher than previous literature values.

Polymers used as materials for optical application require good transmission behavior; the refractive index and Abbe number are other important parameters. Polymethacrylates exhibit a considerable range of refractive indices; plastics with a particularly low refractive index have been in demand for polymer optic fibers (POF). Fluorinated polymethacrylates are particularly suitable in this connection. A summary of relevant data (T_g, n_D^{20}) is given in [18].

The influence of tacticity on the refractive index and density should also be taken into account, but up to now little information has been available.

3. Raw Materials

The starting material for PMMA is the monomer methyl methacrylate (MMA). The most important route to this monomer (as well as to methacrylic acid) is still methanolysis (or hydrolysis) of methacrylamide sulfate. The latter is produced from acetone and hydrogen cyanide via the intermediate acetone cyanohydrin. Alternative synthesis pathways have also been adopted: the C-4 route involves two-stage oxidation of isobutene (or *tert*-butanol) to methacrylic acid and MMA. In the C-3 route propene is reacted with carbon monoxide to give isobutyric acid, from which methacrylic acid is then obtained by oxidative dehydrogenation. The C-2 pathway involves condensation of propanal (or propionic acid) with formaldehyde to methacrolein (or methacrylic acid). Propanal can be obtained from ethylene by hydroformylation. For further details of the synthesis of methacrylic acid and MMA, see → Methacrylic Acid and Derivatives, Chap. 3.

MMA for polymerization is usually available with a purity of >99.9 %; impurities are mainly water, methanol, and traces of acid.

MMA is stabilized for storage or transportation with phenol derivatives (e.g., hydroquinone or hydroquinone monomethyl ether) in amounts of 10 – 100 ppm; the stabilizing action of these compounds requires the presence of oxygen. Nitrogen oxides or aromatic nitro compounds can be used in the absence of oxygen. MMA should be stored under exclusion of light and at as low a temperature as possible (<10 °C).

To obtain higher methacrylate esters, methacrylic acid is esterified with the relevant alcohols. Longer-chain methacrylate esters are also synthesized by transesterification of MMA.

4. Production Processes

Methyl methacrylate can be polymerized by a free radical mechanism [19, 20] or an anionic mechanism [21–23]. Anionic polymerization is, however, of no industrial importance because the monomer has to be subjected to extensive purification and polymerization has to be performed at low temperatures. The group transfer polymerization technique (GTP) is mechanistically very similar to anionic polymerization, but is less complicated [24, 25]. It remains to be seen whether this polymerization technique will become industrially important.

Radical polymerization of MMA may be carried out homogeneously (bulk or solution polymerization) or heterogeneously (suspension or emulsion polymerization). It can be initiated with radiation (light, γ-radiation), heat, or radical-forming chemical agents. Spontaneous thermal initiation of MMA polymerization is extremely slow [26] and is therefore of no industrial relevance. Photoinitiation of MMA polymerization can be performed without sensitizers, but photochemically labile compounds are generally added. On exposure to light these compounds form radicals either directly (e.g., azo compounds, disulfides, derivatives of benzoin or acetophenone) or are converted into an excited state and then form radicals after abstracting a hydrogen atom from the monomer or solvent (e.g., derivatives of benzophenone or anthraquinone) [27–31]. Initiation of polymerization by γ-rays (e.g., ^{60}Co source) may be of interest if the addition of a thermal initiator is undesirable and a conventional light source cannot be used because the polymerization batch absorbs too

strongly (e.g., colored solutions, porous materials such as wood or stone impregnated with monomer [32]).

The polymerization of MMA is most commonly initiated by using thermal radical-forming agents (i.e., initiators). Azo compounds [33,34] and organic peroxy compounds [34] (diacyl peroxides, dialkyl peroxides, alkyl peresters, peroxy dicarbonates, perketals, alkylhydroperoxides) are often employed. A wide range of initiators is available so that the polymer manufacturer can select an initiator with an appropriate half-life for the relevant polymerization temperature. Redox systems also play an important role in the formation of initiating radicals, particularly in polymerizations in aqueous solution [35].

The polymerization of MMA up to high conversion (particularly in bulk polymerization) is governed by the gel (Trommsdorff) effect [36]. The extremely large increase in the viscosity of the reaction medium during polymerization hinders diffusion of the polymer radicals considerably. Bimolecular chain termination thus becomes increasingly difficult and the concentration of the growing radicals increases by several orders of magnitude. The result is a sharp rise in the polymerization rate and mean molecular mass [37], which leads to a further increase in the viscosity of the reaction batch. Under these circumstances removal of the heat of polymerization (57.7 kJ/mol for MMA [38]) may become a serious problem or even a potential hazard.

When polymerization is combined with a shaping or forming operation, the considerable decrease in volume associated with polymerization of the monomer may also lead to problems. For the bulk polymerization of MMA shrinkage can be described by the following equation:

$$v = v\,(1 + e \cdot x)\,\mathrm{M} \tag{3}$$

where v_{M} and v denote the specific volumes of the pure monomer and reaction mixture respectively, x is the degree of conversion, and ε is the contraction constant. The dependence of ε on the reaction temperature θ (in °C) is given by [39]:

$$\varepsilon = -0.2256 - 4.81 \times 10^{-4}\theta - 4.1 \times 10^{-7}\theta^2 \tag{4}$$

At 60 °C, for example, the volume shrinkage of a fully polymerized sample amounts to 25.6 %. Shrinkage decreases with an increase in the size of the alcohol residue of the methacrylate; ε calculated on a molar basis remains roughly constant, however.

The method selected for the industrial polymerization of MMA (e.g., bulk, bead, emulsion, or solution polymerization) is generally governed by the form in which the polymer is finally used. Semifinished products (sheets, blocks, rods, tubes) or pellets, beads, dispersions, and solutions may be produced.

4.1. Bulk Polymerization

Sheets, rods, and tubes of PMMA can be produced by extrusion of molding powders or by bulk polymerization of monomers or "syrup." The molding powder is obtained by bulk, suspension, emulsion, or solution polymerization.

4.1.1. Casting of Acrylic Glass

The conventional casting process is still the most important method for producing high-quality acrylic glass with a mirror-smooth surface (e.g., Plexiglas GS, Perspex, or Vedril). Casting molds are used that consist of two plane-parallel silicate glass plates (e.g., float glass with a typical length, width, and thickness of 3000, 2000, and 8 mm, respectively) which are held apart by a spacer (sealing) and clamped together with metal clamps. The sealing thread runs around the edge of the plates and is usually made of poly(vinyl chloride) or ethylene – vinyl acetate copolymer. It must have sufficient compressibility to allow for the shrinkage occurring during polymerization so that the acrylic sheet does not become detached from the glass plates. The thickness of the resulting sheets is between a few millimeters and up to ca. 30 cm.

The reaction solution consisting of monomer, initiator, and other additives (e.g., comonomers, cross-linking agents, stabilizers, flame retardants, dyes, or pigments) is introduced into the chamber through a small hole in the sealing. Care must be taken to avoid formation of air bubbles, if necessary the solution should first be evacuated. A monomer – polymer solution (syrup) may be used instead of the monomer

solution. This syrup contains 5 – 20 % PMMA and is obtained by prepolymerization of MMA in a stirred-tank reactor. It is advantageous in that the shrinkage and heat of polymerization in the chamber are lower, and the polymerization time is also reduced. Furthermore, the viscous syrup ensures better dispersion of pigments and prevents leakage from the chamber.

The contents of the sealed cells are polymerized in horizontal wracks mounted in hot-air ovens with a high air circulation rate, in autoclaves using spray water (90 – 100 °C), or in water tanks (20 – 60 °C). The residence time may range from a few hours to several days depending on the sheet thickness. Conversion only reaches 80 –90 %, however, because the glasslike solidification of the reaction mixture that occurs during polymerization below the glass transition temperature of the pure polymer prevents further reaction (glass effect). Subsequent polymerization at 110 – 120 °C is therefore necessary to obtain maximum conversion [17,40]. After cooling to room temperature, the polymer sheet is separated from the glass plates and can be removed. The glass plates are cleaned before being used again.

The conventional casting process described above is labor-intensive and time-consuming; attempts have therefore been made to develop more efficient methods for producing cast PMMA glass. One approach is to pack several plane-parallel glass plates and spacers together. The simplest case is a double cell (three plates with two spacers). More complex constructions have been known for a long time and include a process patented in 1933 in which several glass plates with intermediate seals are stacked in vertical rows. The plates are enclosed on both sides by heatable and coolable metal chambers through which a heat-transfer agent flows, and are held together by a screw press [41,42]. The heat-transfer agent flowing through the metal chambers allows accurate temperature control. Shrinkage is compensated for by compression of the packet, resulting in strict tolerances of the cast sheets.

In a special variant of this process, the entire apparatus is tightly encapsulated to facilitate degassing of the reaction batch by evacuation. The system is then pressurized to suppress the formation of boiling bubbles caused by local superheating during polymerization. The advantages of this method are the smaller space requirement and reduced workforce. A disadvantage is the fact that the use of metal chambers means that there is less flexibility as regards variation of the sheet sizes. The process is still used on a small scale in Europe (Rostero) and in the United States (Polycast Corp).

In addition to the production of high molecular mass, high-quality, optical acrylic glass, casting polymerization is still occasionally used to produce regular molding compounds and paint resins. Since these products must not have the perfect plane-parallel surfaces required in semifinished products, cells made of steel or aluminum sheet metal are generally used that are lined with a film (e.g., polyester film). The cells thus enclose polymerization sacks that allow simple mechanical handling. After polymerization the film is removed and the polymethacrylate sheet is ground and granulated in an extruder; residual monomer is removed by degassing. For economic reasons this procedure is only used on a small scale.

4.1.2. Continuous Production of Cast Acrylic Glass

The improvements in the conventional chamber process described in Section 4.1.1 cannot disguise the fact that batch production of acrylic glass is relatively complex and labor-intensive. There have therefore been many attempts to develop continuous processes; the best-known of these is the double-belt process which allows efficient production of large series of sheets up to ca. 6 mm thick [43–46]. The MMA – PMMA syrup is continuously fed between two endless, highly polished steel belts (width up to 3 m, length ca. 250 m). The belts are sealed at the edge with flexible plastic hoses (e.g., of PVC) and guided at a rate of about 1 – 3 m/min over roller systems through several accurately controlled temperature zones. The continuous product sheet can either be wound on rollers or cut into rectangles. This process was first used in the United States by Swedlow and subsequently by Rohm & Haas, Mitsubishi, and Du Pont. The surface quality of the acrylic glass product depends solely on the polishing of the steel belt; the brilliance of acrylic glass produced by the cell polymerization process is seldom ob-

tained. Polymerization in the double-belt process is faster than in the conventional casting process, resulting in somewhat lower molecular masses and therefore some minor deterioration of mechanical properties.

4.1.3. Tube Polymerization

Tubes of PMMA can be produced by extrusion from a molding compound, but also by a special type of bulk polymerization, i.e., centrifugal polymerization [47]. Monomer or syrup is fed into tubular molds (e.g., of stainless steel) that are rotated during polymerization. A film is produced on the internal wall of the pipe by centrifugal forces and polymerizes to form pipes of specific diameter (13 – 650 mm) and wall thickness (1 – 10 mm). This technique is extremely labor-intensive and requires high-precision apparatus. Centrifugal polymerization is therefore seldom used on an industrial scale.

4.2. Suspension Polymerization

PMMA can be produced in the form of small beads by suspension polymerization [48,49]. The monomer (with or without comonomer) is stirred with about twice its volume of water and dispersants (distributors). A dropletlike distribution of the monomer phase in water is then formed. The droplets become increasingly viscous during the course of polymerization. The distributors stabilize the suspension and prevent the droplets from adhering to one another during collisions. Gelatin, cellulose derivatives, synthetic, water-soluble polymers [e.g., poly(vinyl alcohol) or alkali salts of (co)polymers of methacrylic acid] [50], and finely suspended inorganic substances (kaolin, magnesium carbonate, pre-cipitated aluminum hydroxide) have proved suitable as distributors [51,52]. The particle size can be controlled within wide limits (50 – 1000 μm) by choosing appropriate stirring conditions and distributor systems [53].

Suspension polymerization is initiated by adding radical-forming agents, whose distribution equilibrium between the aqueous and the monomer phases should be in favor of the monomer. This also applies to other polymerization auxiliaries, such as chain-transfer agents. The mechanism of suspension polymerization corresponds to that of bulk polymerization. One of the main advantages of suspension polymerization is the extremely high surface to volume ratio of the polymerizing phase. This facilitates removal of the heat of polymerization, which permits higher polymerization rates and thus higher space – time yields than in bulk polymerization. Another advantage is the substantially lower viscosity of the suspension.

After the completion of polymerization, the polymer beads are separated from the aqueous phase (e.g., by filtration), washed with water to remove adhering distributor and salts, and dried.

4.3. Continuous Polymerization of Molding Compounds

The continuous production of cast acrylic glass is of minor importance compared with the batch casting process (see Section 4.1.2). Continuous polymerization processes for the production of PMMA used as injection molding and extrusion material are, however, of major interest. These molding compounds often contain a small proportion of acrylate ester as comonomer (up to ca. 20 %) and have a relatively low weight-average molecular mass (100 000 – 200 000) compared with cast acrylic glass.

The oldest continuous process for producing molding compounds is similar to the double-belt process described in Section 4.1.2 [54,55]: syrup is metered into an endless hose of sheet material and polymerized by passage through a water bath (ca. 75 °C) and an annealing oven (ca. 110 °C). In a plant with a total length of ca. 50 m the residence time is about 1 h.

Technically more elegant processes are generally performed in two stages. In the first stage the monomer is continuously prepolymerized at high temperature (130 – 170 °C) in a stirred-tank reactor. With residence times of 4 – 5 h conversions of 40 – 80 % are obtained. The highly viscous polymer is fed into an extruder. In older processes, the aim was to achieve maximum polymerization in the extruder [56,57]. These techniques are, however, relatively complex and the high polymerization temperatures cause problems with the ceiling equilibrium [38] and thus result in a lower efficiency. More economic processes [58–65] dispense with high conversion in

the extruder. Instead, residual monomer is removed in the degassing zone and recycled to the metering feed device of the stirred tank reactor (if necessary after processing).

The extruded polymer can be pelletized. In order to produce colored pellets, dyes or pigments are mixed with the polymer melt before it is fed into the degassing extruder. Further additives such as chain-transfer agents for adjusting the molecular mass, lubricants, and stabilizers are added either to the melt or to the stirred-tank reactor.

4.4. Batchwise Solution Polymerization

The continuous two-stage polymerization of MMA described in Section 4.3 can be carried out both in bulk and in solution. Batchwise solution polymerization of MMA and in particular of longer-chain methacrylates is also of interest, especially if the resultant polymer solutions constitute the form in which the polymer is used. Typical examples include adhesives and paint resins (see also → Adhesives; → Paints and Coatings, Chap. 2.5.; → Polyacrylates) or additives for the mineral oil sector. Criteria for the choice of solvents include price, solvent quality, toxicity, flammability, boiling point, and the chain-transfer action during polymerization. Solution polymerization can be performed batchwise or with a continuous feed. In order to remove the heat of polymerization it may be advantageous to operate under evaporative cooling conditions.

4.5. Emulsion Polymerization

Methacrylates play an important role as comonomers for acrylates (see → Polyacrylates) and other vinyl compounds (e.g., vinyl acetate) in the production of aqueous plastics dispersions, which are used as paint resins, paper coating agents, textile binders, paper processing agents, and auxiliaries for leather treatment (→ Leather, Chap. 8.4.). Colloidal dispersion and film-forming properties can be widely varied by adding small amounts of methacrylic acid, methacrylamide, or its methylol or methylol ether derivatives. Dispersions of pure polymethacrylates do not, however, form films.

Emulsion polymers with a core – shell structure that contain methacrylates as monomers have become important. Such emulsion polymers are used as impact-resistant modifiers [66] for PMMA [67–69] or other thermoplastics [70, 71]. The solids of a dispersion can be produced by spray drying, freeze coagulation, or squeezing out in an extruder.

5. Uses

Bulk polymers produced from MMA are generally more expensive than many other plastics. Their use is therefore only justified if their special advantages can be fully exploited. These advantages include low density, resistance to fracture, and, above all, excellent optical properties (transparency, gloss) and weather resistance. PMMA also has favorable processing properties (especially good thermoforming) and can be modified in many ways (e.g., coloring, pigmenting, addition of flame retardants, or surface treatment with scratch-resistant coatings).

PMMA has a wide range of applications, particularly in glazing, roofing, vehicles, machinery, and instruments. Pipelines and vessels made of acrylic glass are also of interest for the storage and transportation of food due to their transparency and lack of smell and taste. Optical components such as lenses, reflectors, prisms, and spectacle lenses are also made from polymethacrylates.

5.1. Molding Compounds

PMMA molding compounds are extremely important and versatile as regards applications and uses. The thermoplastically deformable polymers can be used for injection molding and extrusion. The molecular masses (M_w) of PMMA molding compounds are in the range $(1-2)\times10^5$. The processing temperature is generally between 200 and 280 °C.

5.1.1. Standard Molding Compounds

Standard molding compounds consist of MMA homopolymers and copolymers containing up

to ca. 20 % acrylate esters. The comonomer permits variation of the melt flow rate of the polymers.

Standard molding compounds are processed by injection molding. PMMA is especially suitable for this on account of its high dimensional stability. Typical uses include precision parts such as dials, rulers, and other drawing instruments; optical components such as lenses or spectacles; plastic optical fibers (→ Fiber Optics, Chap. 3.3.); and domestic and household articles. Colored injection-molded parts (e.g., covers for automobile rear lights) represent a very important market.

Standard PMMA molding compounds are also extruded on a large scale into flat sheets (width up to 3 m, thickness up to 20 mm), sinusoidally profiled sheets and rods, as well as hollow shapes, double-skin sheets, triple-skin sheets, and tubes (up to 30 cm diameter). If necessary the extrudates are also subjected to surface treatment by coating or coextrusion (e.g., scratch-resistant, antistatic, or nondrip water spreading coating). After cutting to size and covering with a protective packaging film (e.g., polyethylene) they are then marketed as semifinished products.

Trade names of standard PMMA molding materials include Acrylic/Acrycal (Continental Polymers); Acrylite (CYRO); Acrypet (Mitsubishi); Degalan (Degussa); Delpet (Asahi); Diakon (ICI); Lucite (Du Pont); Lucryl/Resarit (BASF/Resart); Oroglas (Rohm & Haas, in the USA: Plexiglas); Plexiglas (Röhm); Polyacrylate (American Cyanamid); Vedril (Atochem).

The worldwide market for PMMA standard molding compounds is ca. 160 000 – 200 000 t/a, of which Western Europe and the United States each account for ca. 70 000 t/a.

5.1.2. Heat-Resistant Molding Compounds

The long-term service temperatures of articles made of standard molding compounds are considerably below 100 °C. Heat-resistant molding compounds have service temperatures of up to ca. 150 °C. They consist of copolymers of MMA with monomers that stiffen the polymer chains. Examples of such comonomers include maleic anhydride [72] (trade names of copolymers: Acrypet ST, Mitsubishi; Degalan HT 120, Degussa; Delpet 980 N, Asahi; Plexiglas hw 55, Röhm) or also methacrylates with bulky ester groups, such as tricyclodecyl methacrylate [12] (Optorez OZ 1000, Hitachi Chemical).

Chain stiffening can, however, also be achieved by subsequent polymer-analogous reaction of the functional groups in the (co)polymer. For example, adjacent acid groups of a copolymer of methyl methacrylate and methacrylic acid are converted into polymethacrylic anhydride structures under the influence of a strong base [73]. The resulting polymers have Vicat softening temperatures of up to 150 °C, depending on the degree of cyclization. These products are, however, still under development.

Poly(*N*-methyl methacrylimide) [*119499-71-7*] (PMMI), also known as poly(*N*-methylglutarimide), a thermoplastic molding compound, is obtained by reacting PMMA with methylamine, → Polyimides, Chap. 5., [74–76].

PMMI, which is marketed under the trade names Kamax (Rohm & Haas), Pleximid (Röhm), or PMI resin (Mitsubishi Rayon), has favorable optical properties and good weather resistance. It also has a high modulus of elasticity, (ca. 4×10^3 N/mm^2). The Vicat softening temperature of PMMI can be selectively varied via the degree of imidation, and exceeds 170 °C in highly imidated products.

The imidation reaction can be performed in the melt or in solution. Other primary amines besides methylamine can be used. In addition to the glutarimide units resulting from the cyclization and unreacted methyl methacrylate groups, PMMI may also contain varying proportions (depending on the reaction conditions) of structural elements derived from methacrylic acid and methacrylic anhydride.

The market volume for heat-resistant methacrylate molding compounds is estimated at ca. 3000 t/a worldwide and is expected to grow. The most important customers for heat-resistant

molding compounds are the automobile and lighting industries.

5.1.3. Impact-Resistant Molding Compounds

Impact-resistant PMMA molding compounds are multiphase polymer blends based on a soft elastomer phase dispersed in the rigid PMMA matrix. The elastomer phase may consist of EPDM rubbers, poly(butyl acrylate), polybutadiene, and, in rare cases, polysiloxanes. The choice of rubber is especially important for the notched impact resistance at low temperature; acrylic rubbers have a good weather resistance.

The bonding of the disperse elastomer phase to the rigid matrix and its morphology play an important role in determining the mechanical properties of impact-resistant thermoplastics [66]. If the impact-resistant thermoplastics are to be transparent, the refractive indices of the rigid and soft phases must be identical (as long as the domain size of the elastomer phase does not remain below a critical value, e.g., below the wavelength of visible light).

Various methods can be used to produce impact-resistant PMMA: in older processes a suitable type of rubber was grafted with MMA (and comonomers to adjust the refractive index) by bulk or solution polymerization. Increasing conversion leads to phase inversion, whereby the elastomer phase, which frequently includes PMMA (or, in the presence of comonomers, the corresponding copolymer), becomes the disperse phase. This desired morphology and the size of the elastomer particles can be controlled by the viscosity of the reaction medium and the shear forces resulting from stirring. They are then fixed by cross-linking when conversion is nearly complete. Graft polymerization by two-stage suspension polymerization is carried out on an industrial scale, too [48].

Emulsion polymerization is particularly effective if particle size and particle morphology have to be selectively modified (see Section 4.5). Impact-resistance modifiers with a core – shell structure have therefore been developed for PMMA [67–69].

Worldwide demand for impact-resistant PMMA is estimated to be ca. 35 000 – 40 000 t/a. Products in which butadiene constitutes the tough phase include methacry-late – butadiene – styrene (MBS) [*25053-09-2*] (e.g., Plexalloy-F-PAB, Röhm; Cyrolite G 20, CYRO) and methacrylate – acrylonitrile – butadiene – styrene (MABS) [*9010-94-0*] (e.g., Terluran, BASF; Cyrolite XT Polymer, CYRO). PMMA modified with butyl acrylate is commercially available under the trade names Delpet SR (Asahi), Diakon TD (ICI), Lucryl KR (BASF), Oroglas DR (Rohm & Haas), Plexiglas zk (Röhm), and Vedril V (Atochem).

5.1.4. Molding Compounds for Special Optical Uses

PMMA is a highly prized material mainly due to its very good weather resistance, outstanding optical quality, and good processability (e.g., by injection molding). Optical components (e.g., lenses, prisms, mirrors) represent an important area of use for PMMA [77, 78]. The relatively high water absorption of PMMA (ca. 2 %) causes dimensional changes and change in refractive index. This disadvantage can be overcome by using cycloaliphatic methacrylates such as cyclohexylmethyl methacrylate [79] or tricyclodecyl methacrylate [12] as comonomers. Other methacrylates are used in soft contact lenses, in particular the hydrophilic poly(2-hydroxyethyl methacrylate) [80, 81].

The excellent optical properties of PMMA (especially its low orientation birefringence) favor its use as a substrate for optical data storage media. However, in asymmetric, single-sided audio compact discs the relatively high water absorption of the polymer and the associated warpage may detract from these advantages [82, 83]. This problem does not arise with the two-sided video disc; PMMA molding materials are therefore used for these products [84]. See also → Information Storage Materials, Chap. 2.3.2.

A relatively promising area of use for extremely pure PMMA is plastic optic fibers (POF) [85, 86], → Fiber Optics, Chap. 3.3. The theoretical limiting values of transmission loss of PMMA in the 650 and 567 nm minima of the damping spectrum are 100 and 27 dB/km, respectively [87]. Limits of 5 – 6 dB/km at 680 and 650 nm can be achieved with special deuterated or fluorinated methacrylates [88]. PMMI (see

Section 5.1.2) could become important as heat-resistant core material for POFs.

PMMA is also employed in lithographic materials in semiconductor technology. Use as a high-resolution positive resist is based on the depolymerization of this polymer by radiation, see → Imaging Technology. The irradiated regions are accurately dissolved out with suitable solvents. Sensitivity to electron beams and UV light can be increased further by copolymerization with suitable monomers [89, 90].

5.2. Semifinished Products

5.2.1. Extruded Acrylic Glass

A substantial proportion of standard PMMA molding compounds (and in the United States particularly impact-resistant PMMA) is extruded into semifinished products (sheets, double- and triple-skin sheets, corrugated profile sheets, tubes) [91]. Reference has already been made to possible surface modifications of these extrudates (see Section 5.1.1). Cast acrylic glass with a matt surface is difficult to produce, extruded semifinished products with matt surface structures are therfore an interesting alternative. It would be desirable if such products could also be thermoplastically formed without losing their matt structure. One possible solution might be the addition of a highly cross-linked bead polymer to the extrusion compound which would certainly open up new applications extending beyond the traditional areas of use of illuminated advertising signs, projection systems, and picture glass.

The most important market sectors for extruded semifinished products are illuminated advertising signs and glazing (including lighting domes). In Europe the market volume is ca. 70 000 t/a. Important trade names include Acrylite FF (CYRO); Altulex and Vedril E (Atochem); Deglas (Degussa); Perspex TX (ICI); Plexiglas XT and Plexiglas SDP (Röhm).

5.2.2. Cast Acrylic Glass

The substantially more economic production of extruded acrylic glass has led to a considerable decline in the production of cast semifinished products. Nevertheless, cast material has retained its position in applications with stringent requirements as regards surface quality and optical properties. For example, high growth rates for cast acrylic glass are found in the sanitary ware sector (e.g., baths, shower units, and washbasins). On account of certain deficiencies revealed by the hot water alternating test (DIN EN 198), (co)extruded products have still not been widely accepted in this sector.

A more recent use of cast acrylic glass (optionally with flame retardants) are noise protection walls on motorways. This market sector is expected to show a high growth rate. Large sheets ($\geq 2\times4$ m) are needed to prevent drivers from being disturbed by the frames used for mounting.

Aviation glazing, one of the oldest applications of cast acrylic glass, has become increasingly important on account of the enormous increase in air traffic. Acrylic glass has the advantages of low density and outstanding resistance to extreme weather conditions (high UV radiation intensities at high altitudes). In order to improve strength, biaxially stretched polymer is often used. The extremely stringent optical requirements [e.g., freedom from optical distortion, low deflection, lack of internal defects (e.g., bubbles, inclusions), lack of surface defects (e.g., pimples)] predestine cast acrylic glass for aviation glazing. Aviation standards prohibit the use of extruded material.

The total market volume for cast acrylic glass in Europe is ca. 90 000 t/a. Important trade names and manufacturers include Acrylite (CYRO); Altuglas, Casocryl, and Vedril C (Atochem); Paraglas (Degussa); Paralinx (Kyowa Gas); Perspex (ICI); Plexiglas GS (Röhm); Plexiglas (Rohm & Haas, United States); Resartglas (BASF); Shinkolite (Mitsubishi); Sumipex (Sumitomo Chemical).

5.3. Binders and Paints

Methacrylates are used in large amounts as comonomers in the production of acrylate–methacrylate copolymers for binders and paint resins (→ Paints and Coatings, Chap. 2.5.). Methacrylate is often used in this connection to obtain the desired glass transition temperature.

The use of such copolymers in the form of solution polymers, aqueous dispersions, or solid products extends over a wide field (e.g., weather-resistant paints, textile binders, paper coating materials, and adhesives); further details are given elsewhere, see → Polyacrylates.

5.4. Additives for the Petroleum Industry

Long-chain poly(alkyl methacrylates), PAMA, are used as additives in the petroleum sector for many purposes [92–95]. The best-known application is probably their use as viscosity index improvers in engine and gear oils (→ Lubricants and Related Products, Chap. 7.1.). At low temperatures viscosity index improvers increase the viscosity of the mixture only slightly. At high temperatures, however, they compensate for the sharp decrease in viscosity of the base oil by virtue of their intrinsically high contribution to the solution viscosity of the whole system.

This is because the mineral oil becomes an increasingly better solvent for PAMA at higher temperatures and the polymer coils expand greatly. Viscosity index improvers thus prevent destruction of the lubricating oil film and resultant damage to the engine. Viscosity index improvers are generally constituents of an extremely complex additive formulation and interact with other components not only in improving flow behavior, but also in cleaning the engine, dispersing dirt and contaminants, and preventing oxidation of the oil. This dispersing effect can be achieved by incorporating polar comonomers (e.g., *N*-vinylpyrrolidone) into the PAMA chain.

PAMA-based additives also act as pour-point depressants (→ Lubricants and Related Products). The pour point denotes the temperature at which an oil solidifies as a result of precipitation of paraffins. At concentrations of less than 1 %, PAMAs hinder the growth of paraffin crystals and thus prevent the formation of aggregates of crystal needles. The oil remains free-flowing and the oil pump is able to function during cold starting.

5.5. Miscellaneous Uses

Polymethacrylates are used in many applications besides those described in Sections 5.1, 5.2, 5.3, 5.4.

Most poly(vinyl chloride) processing auxiliaries consist of high molecular mass polymers based on MMA. They are generally marketed in powder form as spray-dried emulsion polymers [96]. Important examples of such products include Diakon APA (ICI), Kane ACE (Kanegafuchi Chemical), Metablen (Mitsubishi Rayon), Paraloid K (Rohm & Haas), and Vestiform (Hüls).

Methacrylate reaction resins (monomer–polymer systems) are used in the building industry in mortars and concretes, and in synthetic floor screeds [97, 98].

Alkali-soluble suspension polymers, e.g., Rohagit (Röhm), are used as thickeners for aqueous dispersions and cosmetics, as sizings and finishes in the textile industry, and as dispersion and stabilizing auxiliaries in suspension polymerization. Cation-exchange resins can be obtained by hydrolysis of PMMA, thus producing weakly acidic carboxylic functions (→ Ion Exchangers, Chap. 2.2.1.).

Polymethacrylates are used as dental materials for fillings, false teeth, and prostheses [99], and in surgery as a bone cement for implants. Examples of such products include Kallodoc (ICI) and Plexidon (Röhm).

Coatings of polymethacrylate copolymers such as Eudragit E-30 D [*9010-88-2*] or Eudragit RS [*39316-06-8*] (Röhm) are used as galenic auxiliaries for controlled-release tablets [100, 101].

6. Toxicology

No toxic effects of PMMA have been described, and the polymer is regarded as inert and nontoxic. In individual cases, however, contact of the mucous membranes with polymer powders or dusts may cause allergic and irritating reactions. Skin reactions (presumably due to residual monomer) and asthma have also been noted [102, 103].

Since PMMA is used as a bone cement, its potential carcinogenic effect has been monitored in animal implant tests. Malignant tumors were

found in some cases at the implant site, but also occurred with inert materials of the same shape. Such tumors are therefore most likely to be foreign-body carcinoma resulting from mechanical irritation. Tumors have not yet been observed in humans after many years' use [102].

7. Environmental Aspects

In contrast to most other polymers, PMMA can be almost quantitatively depolymerized to the monomer at high temperature. Conversion of production waste and waste from semifinished product blanks to MMA by cracking had already been investigated at the start of large-scale industrial production in the 1930s [104, 105]. In these earlier processes the polymer was mixed with sand and depolymerized batchwise in retorts or with superheated steam (to avoid local overheating and thus uncontrolled pyrolysis). Continuous processes now operate with an indirectly heated fluidized bed and are substantially more economical [106–108].

1. Polyethylene

Kenneth S. Whiteley

1.1. Introduction

Despite ethylene's simple structure, the field of polyethylene is a complex one with a very wide range of types and many different manufacturing processes. From a comparatively late start, polyethylene production has increased rapidly to make polyethylene the major tonnage plastics material worldwide (45×10^6 t capacity in 1995). In the 1920s research into the polymerization of unsaturated compounds such as vinyl chloride, vinyl acetate, and styrene led to industrial processes being introduced in the 1930s, but the use of the same techniques with ethylene did not lead to high polymers. The chance observation in 1933 by an ICI research team that traces of a waxy polymer were formed when ethylene and benzaldehyde were subjected to a temperature of 170 °C and a pressure of 190 MPa, led to the first patent in 1936 and small-scale production in 1939. The polymers made in this way, by using free radical initiators, were partially crystalline, and measurement of the density of the product was quickly established as a means of determining the crystallinity. Due to the side reactions occurring at the high temperatures employed, the polymer chains were branched, and densities of 915 – 925 kg/m^3 were typically obtained. The densities of completely amorphous and completely crystalline polyethylene would be 880 and 1000 kg/m^3, respectively.

During the 1950s three research groups working independently discovered three different catalysts which allowed the production of essentially linear polyethylene at low pressure and temperature. These polymers had densities in the region of 960 kg/m^3, and became known as high-density polyethylenes (HDPE), in contrast to the polymers produced by the extensively commercialized high-pressure process, which were named low-density polyethylenes (LDPE). These discoveries laid the basis for the coordination catalysis of ethylene polymerization, which has continued to diversify. Of the three discoveries at Standard Oil (Indiana), Phillips Petroleum, and by KARL ZIEGLER at the Max-Planck-Institut für Kohlenforschung, the latter two have been extensively commercialized. More recently the observation that traces of water can dramatically increase the polymerization rate of certain Ziegler catalysts has led to major developments in soluble coordination catalysts and later their supported variants.

The coordination catalysts allowed for the first time the copolymerizaton of ethylene with other olefins such as butene, which by introducing side branches reduces the crystallinity and allows a low-density polyethylene to be produced at comparatively low pressures. Although Du Pont of Canada introduced such a process in 1960, worldwide the products remained a small-volume specialty until 1978 when Union Carbide announced their Unipol process and coined the name linear low-density polyethylene (LLDPE). In addition to developing a cheaper production process, Union Carbide introduced the concept of exploiting the different molecular structure of the linear product to make tougher film. Following this lead, LLDPE processes have been introduced by many other manufacturers.

The history of these discoveries is covered in [1-4], [20].

The three types of polyethylene outlined above account for the major part of polyethylene production (Table 1), but the picture is slightly confused since many plants have the capability of producing more than one type of product (so- called swing plants). Additionally, copolymers are made by both types of process. The free-radical process is used to produce copolymers of vinyl acetate, acrylates, methacrylates, and the corresponding acids, but chain transfer prevents the use of higher olefins because of the drastic reduction in molecular mass of the polymer. The coordination catalysts are able to copolymerize olefins, but are deactivated by more polar materials. Because of the complex interplay of the capabilities of modern plants, it is convenient to treat separately the products, the catalysts, and the processes.

Table 1. Polyethylene production capacities in 10^3 t/a * (1995)

	North America	Western Europe	Eastern Europe	Japan	Rest of World	Total

* Data from Chem Systems, London.

1.2. Properties of Polyethylenes

1.2.1. *Molecular Structure and Morphology*

Figure 1 shows schematic structures for the three polyethylenes, with the main features exaggerated for emphasis. LDPE has a random long-branching structure, with branches on branches. The short branches are not uniform in length but are mainly four or two carbon atoms long. The ethyl branches probably occur in pairs [21], and there may be some clustering of other branches [22]. The molecular mass distribution (MMD) is moderately broad.

Figure 1. Schematic molecular structure

A) Low-density polyethylene; B) Linear low-density polyethylene; C) High-density polyethylene

LLDPE has branching of uniform length which is randomly distributed along a given chain, but there is a spread of average concentrations between chains, the highest concentrations of branches being generally in the shorter chains [23]. The catalysts used to minimize this effect generally also produce fairly narrow MMDs.

HDPE is essentially free of both long and short branching, although very small amounts may be deliberately incorporated to achieve specific product targets. The MMD depends on the catalyst type but is typically of medium width.

Polyethylene crystallizes in the form of platelets (lamellae) with a unit cell similar to that of low molecular mass paraffin waxes [24]. Due to chain folding, the molecular axes are oriented perpendicular to the longest dimension of the lamella and not parallel to it as might be expected (Fig. 2). The thickness of the lamellae is determined by the crystallization conditions and the concentration of branches and is typically in the range of 8 – 20 nm. Thicker lamellae are associated with higher melting points and higher overall crystallinities. Slow cooling from the melt or annealing just below the melting point produces thicker lamellae. Where long molecules emerge from the lamella they may either loop back elsewhere into the same lamella or crystallize in one or more adjacent lamellae, thereby forming “tie molecules”.

Figure 2. Folded-chain lamellar crystal of polyethylene

Thermodynamically the side branches are excluded from the crystalline region because their geometry is too different from that of the main chains to enter the crystalline lamellae. Therefore, the branches initiate chain folding, which results in thinner lamellae with the branches mainly situated on the chain folds on the surface of the lamellae. However, on rapid cooling these energetically preferred placements may not always occur, and some branches may become incorporated as crystal defects in the crystalline regions. Detailed measurements by solid-state NMR and Raman spectroscopy show that the categorization into crystalline and amorphous phases is too simplistic and a significant fraction of the polymer is present in the form of an “interfacial” fraction which has neither the freedom of motion of a liquid, nor the well-defined order of a crystal [25], [26]. A further result of a side branch is that having been prevented from folding directly into the same lamella, the polymer chain may form a tie molecule that links to one or more further lamellae.

Under moderately slow cooling conditions, crystallization may be nucleated at a comparatively small number of sites. Crystallization then propagates outwards from these centers until the surfaces of the growing spheres meet. The resulting spherulites show a characteristic banded structure under a polarizing optical microscope. The typical milkiness of polyethylene is due to light scattered by spherulites or other, less well defined aggregates of crystallites, rather than by the crystallites themselves, which are much smaller than the wavelength of light [27]. Ethylene copolymers may be transparent, although partially crystalline.

1.2.2. *General Properties*

LDPE and LLDPE are translucent whitish solids and are fairly flexible. In the form of films they have a limp feel and are transparent with only a slight milkiness. HDPE on the other hand is a white opaque solid that is more rigid and forms films which have a more turbid appearance and a crisp feel.

Polyethylene does not dissolve in any solvent at room temperature, but dissolves readily in aromatic and chlorinated hydrocarbons above its melting point. On cooling, the

solutions tend to form gels which are difficult to filter. Although LDPE and LLDPE do not dissolve at room temperature, they may swell in certain solvents with a deterioration in mechanical strength. Manufacturers issue data sheets detailing the suitability of their products for use in contact with a wide range of materials. In addition to solvents, polyethylene is also susceptible to surface active agents which encourage the formation of cracks in stressed areas over prolonged periods of exposure. This phenomenon, known as environmental stress cracking (ESC), is believed to be due to lowering of the crack propagation energy [28]. In general, HDPE is the preferred polyethylene for liquid containers.

Some properties of typical LDPE, HDPE, and LLDPE are listed in Table 2. Polyethylenes are routinely characterized by their density and melt flow index (MFI). The MFI test was originally chosen for LDPE to give a measure of the melt characteristics under conditions related to its processing. It is carried out by applying a standard force to a piston and measuring the rate of extrusion (in g/10 min) of the polyethylene through a standard die (Fig. 3). Other standard conditions are sometimes used on the same equipment to extend the range of information and because higher loads are sometimes considered more appropriate for HDPE. The short parallel section of the standard die introduces errors which mean that the MFI cannot be accurately related to viscosity (it would be an inverse relationship). For LDPE and HDPE, the MFI increases disproportionately with the applied load. The ratio of the two MFIs gives a measure of the ease of flow at high shear and is sometimes known as the flow ratio. The die swell ratio can also be measured in the MFI test and gives a measure of the elastic memory of the melt. This parameter correlates usefully with extrusion processes, where a low value is desirable for tubular film, and a high value is necessary for extrusion coating.

Table 2. Properties of some typical polyethylenes (data from Repsol Quimica)

The behavior of polyethylene under shear is shown in Figure 4, which compares a LDPE and a LLDPE similar to those in Table 2. At sufficiently low shear rates the viscosity of all polyethylenes becomes Newtonian, i.e., independent of shear rate. Due to its narrow MMD the viscosity of the LLDPE is less shear dependent than that of the LDPE and has a higher viscosity under the higher shear conditions used in processing equipment.

Figure 4. Dependence of viscosity η on shear rate $\dot{\gamma}$ for two polyethylenes

a) Low-density polyethylene; b) Linear low-density polyethylene; c) Apparent shear rate in melt flow index test

As indicated above, the crystalline properties are affected by the rate of cooling from the melt and the subsequent thermal history. For the purposes of reproducibility it is usual to apply a standard annealing treatment to test samples, such as annealing at 100 °C for 5 min followed by slow cooling to room temperature. The crystallinity correlates with the density, reflecting the average properties of the polymer, but the melting point and the softening points for LLDPE are higher than for LDPE due to the presence of some relatively sparsely branched species in the former type of polymer. In addition to the differential scanning calorimetry (DSC) technique used to measure the fusion point, the relative heterogeneity of the LLDPEs is demonstrated even more clearly by temperature rise elution fractionation (TREF) [29], [30]. After depositing the sample by slow cooling from solution onto an inert support, elution is carried out over a programmed temperature range to measure the concentration of eluted polymer as a function of elution temperature. Examples are shown in Figure 5. LLDPE produced with a single-site catalyst (see Section Single-Site Catalysts (Metallocenes)) shows a single sharp peak by this test.

Figure 5. Temperature rise elution fractionation curves (*I* is the cumulative weight fraction)

The weight-average and number-average molecular masses determined by size exclusion chromatography (SEC, also known as gel permeation chromatography, GPC) are listed in Table 2, and Figure 6 shows their molecular mass distribution curves.

Figure 6. Molecular mass distribution curves for the polyethylenes of Table 2 (data from Repsol Quimica)

I is the cumulative weight fraction.

In the tensile test the yield strengths and the elastic moduli are as expected from the respective crystallinities. The higher rupture strength of the LLDPE relative to the LDPE is typical when the two polymers are chosen to have equal MFIs, but if the criterion were constant high-shear extrudability (e.g., the high load MFI) the tensile strengths would be very similar. The example chosen for the LLDPE is a butene copolymer. For higher performance applications longer chain olefins are used as comonomers [31]; e.g., octene (Du Pont, Dow), hexene (UCC, Exxon), 4-methylpentene (BP). These produce higher tensile strengths and impact energies, particularly in the form of film.

In common with other polymers, polyethylene is viscoelastic in the solid state. This means that the strain produced by applying a stress is time dependent, and in defining an elastic modulus it is important to specify the timescale of the measurement. Figure 7 shows the results of a measurement of strain versus time for a HDPE specimen at a constant tensile stress of 6.5 MPa [32]. The strain continues to increase approximately linearly with log *t* and after 4 d would have reached almost four times the value measured after 10 s. Thus the effective Young's modulus after 4 d is only 25 % of the short-term value and after several years would be lower still. This creep behavior is particularly marked in the case of polyethylenes because the amorphous regions are relatively mobile at room temperature [33]. For design purposes the modulus must be estimated for the timescale and temperature expected for the application. A related problem in designing for long-term use is that a prolonged high stress may lead to crack formation and failure at a stress significantly below the conventionally measured yield stress [34].

Figure 7. Tensile creep of HDPE (Rigidex 006–60) [32]

The extremely low loss tangent (power factor) makes LDPE ideally suitable as an insulator for high-frequency cables. Since pure polyethylene contains no polar groups, a very low power factor is expected, and most of the measured value is due to traces of oxidation, catalyst residues, antioxidant, etc. Because they contain Ziegler or Phillips catalyst residues, such low power factors are not generally achievable with HDPE or LLDPE.

Figure 8 shows the permeability of LDPE and ethylene – vinyl acetate copolymer (EVA) films to oxygen and water vapor. Although LDPE has a very useful role as a packaging material, the gas and water vapor permeabilities are not particularly low compared to other film forming materials (see ⟶). Since permeation takes place in the mobile amorphous phase, the permeability of HDPE is appreciably lower.

Figure 8. Permeability *P* of 0.025 mm films of LDPE and EVA at 23°C (data are based on Exxon Escorene Ultra EVA copolymers [35])

a) Oxygen; b) Water vapor (50 % R.H.)

Polyethylene is a high molecular mass hydrocarbon which can be considered as toxicologically inert, and indeed high-purity forms are used in medical prostheses. The suitability of a polyethylene for use in contact with food or in medical prostheses depends on its content of catalyst residues and principally on additives such as antioxidants. Acceptable limits on process residues and additives are normally controlled by national regulatory bodies, but in many cases they are based on the standards defined by the American Food and Drug Administration (FDA) or the German Bundesgesundheitsamt.

1.2.3. *High Molecular Mass (Bimodal) Polyethylene (HMWPE)*

This description is usually applied to HDPEs with MFIs in the range 0.01 – 0.1 by the normal test, although a higher load is usually used to characterize them. They are processable with some difficulty on conventional PE processing machinery, although some advantages can be gained by using equipment optimized for these grades. In general, they are not simply higher molecular mass versions of normal HDPE grades, but are specially designed broad-MMD polymers, often produced by using multiple reactors or combinations of catalysts [36]. The broad MMD, which may be bimodal, produces a highly shear dependent melt viscosity combined with good mechanical strength.

A particularly important type of bimodal polymer is produced by combining a high molecular mass component having a relatively high concentration of short branches with a low molecular mass component containing few or no branches. In this way the low molecular mass component crystallizes as folded chain lamellae and the high molecular mass component forms tie molecules which crystallize in several of the lamellae. This combination of branching and molecular mass is the reverse of what is usually observed in LLDPEs (see Sections Molecular Structure and Morphology and Single-Site Catalysts (Metallocenes)), where the more higly branched components have low molecular masses. The desired bimodal distribution is achieved by careful process modifications using multiple reactors. The optimization of the tie molecules confers excellent resistance to long term crazing and crack growth [37], making the polymers particularly suitable for pipe and liquid containers.

1.2.4. *Ultra High Molecular Mass Polyethylene (UHMWPE)*

These polyethylenes were commercialized shortly after HDPE and have extremely high molecular mass (3 – 6×10^6 according to ASTM D4020), but do not usually have a broad molecular mass distribution. The viscosity is too high to be measured by the MFI test, and they are usually characterized either by the relative solution viscosity in decalin at 135 °C, or by specially developed melt flow tests. The material is processed by techniques similar to those developed for PTFE, which involve fusing by sintering, rather than plastification to a true melt. UHMWPE has a remarkable combination of abrasion resistance, chemical inertness, low friction, toughness, and acceptability in contact with foodstuffs. Some properties are listed in Table 3. The density is only 940 kg/m^3, even though the polymer is unbranched, because the extremely high viscosity hinders the crystallization process.

Table 3. Properties of an ultra high molecular mass polyethylene (Hoechst GUR 412) [38]

Property	UHMWPE	Method	Standard
Molecular mass	4.5×10^6	viscometric	DIN 53 728
Reduced specific viscosity, cm^3/g	2300	0.05 % in decalin	
Density, kg/m^3	940		DIN 53 479
Crystalline melting range, °C	135 – 138	polarizing microscope	
Tensile yield strength, MPa	22		DIN 53 455
Tensile rupture strength, MPa	44		
Elongation at rupture, %	> 350		
Impact energy, notched, kJ/m^2	210	double V-notch	DIN 53 453
Volume resistivity, Ω · m	> 10^{13}		DIN 53 482

1.2.5. *Properties of Ethylene Copolymers*

Table 4 lists the principal types of ethylene copolymers which are in commercial production. Of these the vinyl acetate copolymers are produced in the largest quantities. All the ester and acid copolymers are produced by the high-pressure free-radical process, but most of the plants in the rapidly expanding LLDPE sector have the capability to produce VLDPE copolymers with higher content of α-olefin and this is an area with a large potential for expansion.

Table 4. Principal types of ethylene copolymer

Comonomer	Abbreviation	Feature	Catalysis [*]
Vinyl acetate	EVA	flexibility	FR
Methyl acrylate	EMA	flexibility, thermal stability	FR
Ethyl acrylate	EEA	flexibility at low temperature, thermal stability	FR
Butyl acrylate	EBA	as for EEA	FR
Methyl methacrylate	EMMA	flexibility, thermal stability	FR
Butene	VLDPE	flexibility at low temperature, thermal stability	Z, SS
Hexene	VLDPE	as for butene copolymer	Z, SS
Octene	VLDPE	as for butene copolymer	Z, SS
Acrylic acid	EAA	adhesion	FR
Methacrylic acid	EMAA	adhesion	FR
Methacrylic acid + Na^+ or Zn^{2+} (ionomer)		adhesion, toughness, stiffness	FR
Acrylic acid + Zn^{2+} (ionomer)		adhesion, toughness, stiffness	FR
Carbon monoxide	PK	polyketone, stiffness, high melting	[**]
Norbornene	COC	cycloolefin copolymer, transparency	SS

[*] FR = free radical, Z = Ziegler catalysis, SS = single-site catalyst.
[**] Novel group VIII metal catalyst.

The principal effect of copolymerization is to reduce the crystallinity. The effect is approximately the same for all comonomers on a molar basis, with the exception of propene which can be incorporated into the crystal lattice. At room temperature the amorphous regions of the copolymer (where the comonomer groups are concentrated) are mobile and the effect of introducing a comonomer is to progressively reduce the stiffness (Fig. 9). In addition to the branches due to the comonomer, the branches which occur under the high pressure synthesis conditions also contribute to the reduction in crystallinity. Below room temperature there are differences between ester copolymers due to the differences in the glass transition temperature T_g of the amorphous material. This follows the T_g of the ester homopolymer and results in EEA and EBA copolymers being flexible down to lower temperatures than EVA, with EMMA having the highest T_g. The VLDPEs produced by the LLDPE processes should have the best low-temperature properties, particularly in the case of narrow composition distribution polymers. Properties of three typical EVAs and a VLDPE [42] are listed in Table 5.

Table 5. Properties of ethylene copolymers

Property	EVA (Repsol PA-501)	EVA (Repsol PA-538)	EVA (Repsol PA-440)	VLDPE (DSM TMX 1000) [a]	Condition	Standard
Vinyl acetate content, wt %	7.5	18	28			
Melt flow index, g/600 s	2	2	6	3	190 °C/2.16 kg	ASTM D1238

The methacrylic and acrylic acid copolymers are produced to provide enhanced adhesion, particularly in coextruded films or laminates. Not included in Table 4 are terpolymers in which acid monomers are used together with ester comonomers to improve adhesive properties.

The ionomers are produced by the partial neutralization of acidic copolymers containing 10 wt % of (meth)acrylic acid by sodium or zinc ions. The ionic salts and the unneutralized acid groups form strong interchain interactions, producing a form of thermally labile cross-linking in both the solid and the molten states [43], [44]. The T_g of the amorphous material in ionomers is slightly above room temperature, resulting in a stiffness similar to that of LDPE at room temperature. However, the stiffness of most ionomers decreases rapidly with increasing temperature above 40 °C. The polyketone (PK) and cycloolefin (COC) copolymers are both recent developments in which ethylene is present as a 50 mol % alternating copolymer [45]. The PK materials are believed to be made with a novel group VIII catalyst [46]. They are targeted at medium-stiffness applications and also have good barrier properties for hydrocarbons. The carbonyl group, however, makes the polymers susceptible to degradation by sunlight. The COC materials from Hoechst make use of the remarkable catalyst activity and copolymerization ability of the new single site catalysts [47] (Section Single-Site Catalysts (Metallocenes)) and the high transparency and low birefringence will allow its use in compact discs and transparent packaging.

1.3. Polymerization Chemistry

Heat of Reaction. The heat of polymerization of ethylene is 93.6 kJ/mol (3.34 kJ/g). Since the specific heat of ethylene is 2.08 J °C^{-1} g^{-1}, the temperature rise in the gas phase is ca. 16 °C for each 1 % conversion to polymer. Heat removal is thus a key factor in a commercial polymerization process. Some processes (e.g., ICI autoclave, Unipol fluidized bed) employ only a limited conversion per pass, and the heat of reaction is absorbed by the cool reactants. The unreacted monomer is then cooled in the recycle stage. In other cases (e.g., UCC or BASF tubular and various slurry processes) more surface area or more residence time is provided, and heat is removed through the reactor walls.

1.3.1. *Free-Radical Catalysis*

1.3.1.1. *Introduction*

Free-radical catalysis is used exclusively in the high-pressure process, that is at pressures above 100 MPa. The reason for the use of such high pressures is a combination of historic, economic, and technical factors [39]. Because ethylene is gaseous above its critical temperature of 9 °C, a pressure of ca. 20 MPa would be necessary in any case to achieve a reasonable concentration of monomer. Employing pressures of ca. 200 MPa and temperatures above 160 °C enables the polyethylene produced to dissolve in the unreacted ethylene, and the high reaction rate makes the best use of the very expensive high-pressure equipment. 20 % conversion of the monomer is typically achieved in 40 s. A schematic phase diagram for an ethylene – polyethylene system is shown in Figure 10 [48]. For a more detailed account of the effect of molecular mass and MMD on the phase equilibria, see [49].

Figure 10. Schematic cloud point surface for ethylene – polyethylene [48]

The single-phase ethylene – polyethylene mixture allows the reaction to take place as a classical free-radical-initiated solution polymerization (⟶ Polymerization Processes). Some aspects which are particularly important for ethylene systems are as follows:

1. In addition to the effect of concentrating the gaseous monomer, the pressure also influences the reaction rate constants, as is also the case for liquid systems subjected to high pressures [50]. This is generally considered in terms of a volume of activation, analogous to the energy of activation. High pressure affects the configuration change necessary for the reactants to reach the transition state. The overall contribution of the effect of pressure on the rate constants over the pressure range 0 to 200 MPa is to increase the polymerization rate by a factor of ca. 12 [51].
2. The reaction temperatures employed are also high, an average of ca. 220 °C being typical. In parts of the reactor the temperature may be as low as 140 °C but in other parts may reach over 300 °C. These high temperatures also contribute to the high reaction rates, the activation energy being 32 kJ/mol.
3. The growing polymer chains are linear alkyl radicals and as such are very reactive not merely in the addition to double bonds, but also in abstracting hydrogen atoms from other molecules, thereby forming saturated alkyl chains and new radicals. The process is called chain transfer. Since these hydrogen atom abstraction reactions have higher activation energies than polymerization, they become increasingly important as the polymerization temperature rises. On the one hand they put stringent demands on the monomer purity to avoid traces of compounds which could give rise to chain transfer and thereby reduce the molecular mass, and on the other hand it is possible to use low concentrations of suitable materials (so-called chain-transfer agents or modifiers) to control the polymer molecular mass. Chain-transfer agents which have been used commercially include hydrogen, propane, propene, acetone, and methyl ethyl ketone. Chain transfer to some compounds with very active hydrogen atoms such as propene, and particularly the higher alkenes, can lead to radicals which are insufficiently reactive towards ethylene to reinitiate new chains rapidly, and reduced reaction rates result.
4. Chain transfer can also occur with the polyethylene chains themselves, either to the same growing chain (intramolecular) or to other polyethylene chains (intermolecular transfer). These reactions create the characteristic structural features of LDPE which distinguish it from HDPE. As can be demonstrated with models, the most probable intramolecular chain-transfer reaction is to the carbon atom four carbons back down the chain, which produces butyl groups (Fig. 11 A). This so-called back-biting mechanism was first published by M. J. Roedel of Du Pont [52]. If, after the addition of one ethylene molecule to the newly formed secondary radical, a further back-bite occurs (Fig. 11 B), a pair of ethyl branches or a 2-ethylhexyl group is formed. A further possibility, shown in Figure 11 C, is that a back-bite occurs to a branch point, and the tertiary radical then decomposes into a new short radical, leaving a vinylidene group at the end of the polyethylene chain. This process is the principal chain-termination mechanism in LDPE, and concentrations of vinylidene groups approach one per number average molecule for LDPEs produced at high temperature. These three reactions account for the principal features observed in the infrared spectrum of LDPE, but to a lesser extent other intramolecular transfers also occur [9]. Since the activation energy for transfer is higher than for the polymerization reaction and the activation volume is smaller, branching and unsaturation increase with increasing polymerization temperature and decrease with increasing reaction pressure [53], [54].
5. Intermolecular transfer leads to long branching and broadening of the molecular mass distribution. Since they have more hydrogen atoms available for chain transfer, the long chains tend to be the most highly branched, and there may be branches on the branches. Statistically each new radical produced by initiation or chain-transfer reactions has a range of probabilities of growing to various lengths before being terminated by one of these same chain-transfer or radical combination reactions. The probable length is the same whether the chain grows from a new initiating radical or a branch point. Thus branches are statistically the same length as the backbone itself and, taking into account statistical variations, the branches may in some cases be longer than the initial backbone. Since the long-branching reaction is a chain-transfer mechanism, the average chain length of an unbranched molecule or a branch is shorter than it would be in the absence of the long-branching reaction. The effects of temperature and pressure are similar to those for short branching, but additionally the amount of long branching is proportional to the concentration of dissolved polymer. In principle, this leads to a clear difference between plug flow (tubular) and continuous stirred-tank reactors (CSTRs, autoclaves). Theoretical analyses have been presented for autoclave [55], [56], [57] and tubular [58] reactors.
6. Initiation is very similar to that in many other free-radical polymerizations, but there are some limitations. Initiators are commonly referred to as “catalysts”. In the sense that one mole of initiator will achieve the polymerization of several thousand moles of ethylene this is so, but the initiator is destroyed in the process and so the term is, strictly speaking, incorrect. Oxygen was used as initiator in the early commercial processes because of the ease of introducing it into the process. With the development of high-pressure pumps and new initiators, modern plants are able to maintain more precise control of temperature profiles by the injection of solutions of liquid catalysts. The mechanism by which oxygen forms free radicals is rather complicated, and at lower temperatures oxygen can act as an inhibitor [59]. In the autoclave process the use of oxygen has been largely superseded, but in the tubular reactor process it is still widely used, sometimes in combination with liquid initiators. The two overall limitations on initiators are that they should be readily soluble in alkanes and they should produce reactive radicals, ideally alkyl or alkoxy radicals. On the former count, all the aqueous systems and most azo compounds are excluded, and on the second count dibenzoyl peroxide is unsuitable. The initiators are selected for use on the basis of their half-lifes at the reaction temperature. Since the residence time in the reactor zone may be of the order of 20 s or less, to obtain good control of the reaction rate, an initiator half-life of about 1 s is required. For a tubular reactor the same initiator is active over a wider range of temperatures, but its selection is equally critical. Typical initiators are listed in Table 6 [60].
7. The mechanism of kinetic chain termination is by combination of radicals. This further widens the MMD in long-branched systems when the rate of inititation-combination is high [57].
8. Although the conversion of ethylene to polyethylene is thermodynamically favorable, the decomposition into carbon and a mixture of methane and hydrogen is also highly exothermic:

$$C_2H_4 \rightarrow C + CH_4 \; \Delta H = 127\,\mathrm{kJ/mol}$$

$$C_2H_4 \rightarrow 2\,C + 2\,H_2 \; \Delta H = 53\,\mathrm{kJ/mol.}$$

Table 6. Peroxide initiators for the high-pressure process [60]

Peroxide	Formula	Temperature for half-life of 1 s, °C	Storage temperature, °C
Di-(2-ethylhexyl) peroxydicarbonate	$(C_4H_9)(C_2H_5)CH-CH_2-O-C(=O)-O-O-C(=O)-O-CH_2-CH(C_2H_5)(C_4H_9)$	130	< − 15
tert-Butyl 2,2-dimethylperoxypropanoate	$(CH_3)_3C-O-O-C(=O)-C(CH_3)_2-CH_3$	154	< 0
Di-(3,5,5-trimethylhexanoyl) peroxide	$(CH_3)_3C-CH_2-CH(CH_3)-CH_2-C(=O)-O-O-C(=O)-CH_2-CH(CH_3)-CH_2-C(CH_3)_3$	173	− 10 to 0
tert-Butyl 3,5,5-trimethylperoxyhexanoate	$(CH_3)_3C-O-O-C(=O)-CH_2-CH(CH_3)-CH_2-C(CH_3)_3$	211	< + 30
Di-*tert*-butyl peroxide	$(CH_3)_3C-O-O-C(CH_3)_3$	244	< + 30

Figure 11. Principal intramolecular chain-transfer reactions

For kinetic reasons these reactions are only important at the high temperature and pressures of the high-pressure process. In a confined system the large amount of heat released can raise the temperature, and hence the pressure, of the methane and hydrogen to potentially dangerous levels. The theoretical final temperature and pressure for a contained decomposition starting at 250 °C and 200 MPa are 1400 °C and 620 MPa. In practice much of the heat would be absorbed by the walls of the vessel or pipework. High-pressure plants are designed with relief valves or bursting disks to protect the equipment from overpressurization due to decomposition. Decompositions usually start as a runaway polymerization reaction, but then they can propagate as a slow flame front even into cold gas. Experimental decompositions usually show low propagation velocities of ca. 0.2 m/s [61], but under the more turbulent conditions of commercial plant operation, propagation can be more rapid.

1.3.1.2. *Copolymerization*

High-pressure ethylene copolymerization follows the classical free-radical copolymerization mechanism (⟶ Polymerization Processes). One of the most important characteristics are the reactivity ratios r_1 and r_2. The rates v of the four growth reactions are

$$-R_1^\bullet + M_1 \rightarrow \; -R_1^\bullet \quad v_{11} = k_{11}[R_1][M_1]$$

$$-R_1^\bullet + M_2 \rightarrow \; -R_2^\bullet \quad v_{12} = k_{12}[R_1][M_2]$$

$$-R_2^\bullet + M_1 \rightarrow \; -R_1^\bullet \quad v_{21} = k_{21}[R_2][M_1]$$

$$-R_2^\bullet + M_2 \rightarrow \; -R_2^\bullet \quad v_{22} = k_{22}[R_2][M_2]$$

$$r_1 = k_{11}/k_{12} \; r_2 = k_{22}/k_{21}$$

$-R_1^\bullet$ represents a growing radical where the last unit added is monomer 1 (ethylene for the purpose of this discussion).

For low concentrations of monomer 2 it follows from the well-known copolymerization equation that:

$$1/r_1 = \frac{\text{concentration of monomer 2 in copolymer}}{\text{concentration of monomer 2 in reactor}}$$

The value of r_1 can thus give guidance on the effectiveness of incorporation of comonomer relative to the feed concentration. Some measured values are shown in Table 7. A more comprehensive compilation is given in [9]. Vinyl acetate has a reactivity ratio of almost exactly 1.0 which means that the copolymer has the same composition as the reactor feed. Acrylates on the other hand have r_1 much lower than 1 which means that the copolymer is much richer in acrylate than the reactant mixture. This has implications for the type of reactor. A continuous stirred-tank reactor (CSTR) operates with the comonomer concentrations in a dynamic equilibrium. To make a copolymer containing 20 wt % ethyl acrylate, the feed composition would contain typically 4 % of ethyl acrylate, but the reactor and the stream leaving the reactor would contain only 1.6 %. In the case of a continuous plug flow reactor (CPFR), corresponding to a tubular reactor or a laboratory batch reactor, the corresponding figures would be 3.1 and 0.7 %. The copolymer would in this case be a continuous blend of compositions ranging from 38 % to 9 % produced as the comonomer was used up progressively along the reactor. A useful feature of r_1 for vinyl acetate being 1.0 (and r_2 is also 1.0) is that values of reactivity ratios reported in the literature for other monomers copolymerizing with vinyl acetate can be used to estimate the reactivity ratios for ethylene at high pressure [39]. This is illustrated in Table 7.

Table 7. Copolymerization reactivity ratios and chain transfer [a]

Comonomer M_2	r_1 (rel. to ethylene)	r_1 (rel. to VA) [b]	Chain transfer [c]
Vinyl acetate (VA)	1.05		0.7
Methyl acrylate	0.13	0.1	0.4
Ethyl acrylate	0.08		3.3
Methyl methacrylate	0.06	0.015	2.2
Methacrylic acid	0.015	0.01	
Styrene	0.01	0.01	
Vinyl chloride	0.18	0.23	> 10
Propene	1.3		1.1
Butene	2.0	2.0	20
Isobutene	1.0		2.1

Hexene	1.4	> 20

[a] Reactivity ratios and chain transfer measured in a continuous reactor at 190 °C and 157 MPa, except for the olefins where the data are from a batch reactor at 140 °C and 196 MPa.
[b] Literature values from [40], [41].
[c] d[log(MFI)]/d[M_2] in decades of MFI change per mol % in reaction mixture.

Comonomers also act as chain-transfer agents. Table 7 shows some practical measurements of these effects on the MFI under standard conditions. Reference [9] tabulates the chain-transfer effects in terms of molecular mass reduction. Clearly a moderate chain-transfer activity can be tolerated more readily for a comonomer with a low r_1 since the concentration in the reactor will be lower. The chain-transfer activity of the higher α-olefins such as butene is very high, precluding their use in the free-radical process. The radicals produced by chain transfer are relatively stable and retard the reaction. Propene is less extreme in these effects and is sometimes used in the high-pressure process.

Copolymerization theory shows that if r_2 is greater than 1 (it usually approximates to $1/r_1$), then the overall reaction rate is reduced. In a continuous process this translates to an increased initiator demand which in extreme cases makes the process inoperable. As indicated above for homopolymers, a high initiation rate broadens the MMD. Thus acrylate and methacrylate copolymers require higher initiator injection rates and produce hazier films due to the wider MMD.

1.3.2. *Coordination Catalysis*

The three independent discoveries of low-pressure routes to linear polyethylene had one thing in common: they used catalysts containing transition metals. Despite their very different methods of preparation, there is general agreement that the basic mechanism of polymerization by these catalysts is the same. At some stage a σ-bonded alkyl group is formed. Ethylene is coordinated to the transition metal by a π-bond. This then facilitates the insertion of the ethylene molecule into the metal – alkyl bond producing a longer chain alkyl and a vacant coordination site.

The direct insertion of ethylene into σ-bonded aluminum alkyls was discovered by ZIEGLER in 1950, but the reaction was slow and did not lead to high polymers. The prior coordination of ethylene is clearly crucial. The active species in commercial catalysts is complex, but there is a very large worldwide activity in investigating coordination catalysts, usually by way of model compounds [16], [17]. Commercial catalysts are virtually all heterogeneous solids (at least on a microscopic scale) and require careful attention to the particle shape and size in the development of the manufacturing process. A feature of modern coordination catalysts (except those used in solution processes) is that the catalyst particles grow by a process of replication [13]. This means that the overall shape of each particle is maintained as it grows by polymerization, and thus the distribution of polymer particle sizes is related to the distribution of catalyst particle sizes. For this type of growth to occur, the polymerization process must break down the catalyst particles into much smaller entities which remain held together by the polymer formed, sometimes in the form of fibrils (Fig. 12). Electron microscopy has shown, for one type of supported catalyst at least, that the growth occurs in the form of cylinders, in the growing end of which a catalyst fragment is embedded[62]. This type of growth explains why polymerization rate does not decrease as the overall particle size increases, since the monomer diffusion path remains short. The active catalyst fragments range in size from about 4 nm for $TiCl_3$ to 100 nm for oxide-supported catalysts.

Figure 12. Catalyst particle growth by replication [13]

By suitable technology, catalysts can be prepared so that replication leads to polymer particles with a spherical shape and a diameter of ca. 1 mm, suitable for direct use without a pelletization step. Examples of this are the Phillips Particle Form and UCC's Unipol processes based on silica-supported catalysts, and the Montedison Group's Spheripol catalyst based on $MgCl_2$. Outside the United States there is considerable resistance by fabricators to the direct use of polymer powder, and much of the product is pelletized.

Not being simple isolated molecules, the active catalyst sites are not all identical and their activities and the average chain lengths which they produce vary. Instead of a simple statistical distribution of molecular mass, which would lead to a ratio of weight-average to number-average molecular mass of 2.0, appreciably broader MMDs are obtained (Fig. 13).

Figure 13. MMD curve of a Ziegler HDPE compared with simple statistical theory

a) Most probable distribution; b) Hostalen GD-4755

1.3.2.1. *Phillips Catalysts*

A typical Phillips catalyst is produced by impregnating silica particles with a solution of CrO_3 to give a chromium content of ca. 1 %. The powder is then calcined in a current of air with increasing temperature to a final value of ca. 800 °C. At this temperature all of the physically absorbed water and most of the surface hydroxyl groups are driven off [63] and the chromium is present as surface chromate. The formation of a surface silyl chromate

is significant, because at the calcining temperature CrO_3 would decompose to lower valent oxides. This catalyst, which is now moisture sensitive, will polymerize ethylene, but with an induction period. During the initial reaction with ethylene the catalyst's color changes from orange to blue. This is believed to be due to the reduction to Cr^{2+}. The reduction can also be brought about by treatment with carbon monoxide, and in this case the catalyst reacts immediately with ethylene without an induction period.

The selection and treatment of the support is fundamental to the process, and a plant may use catalysts made from a variety of supports to produce the whole range of products. The optimum silica is claimed to have a high percentage of pores with a pore diameter of 20 – 50 nm. A frequently used grade, Grace Davison 952, combines the required pore characteristics with a microspheroidal form. Where the spherical form is not necessary, other silicas are also used, made from crushed and graded silica gel with the required pore structure. The supports are normally supplied with the chromium already impregnated, leaving only the activation stage to be carried out at the polyethylene plant.

As a means of increasing the catalyst productivity and facilitating the production of lower molecular mass (higher MFI) polymers, treatment with titanium compounds is

frequently used [64]. The resulting polymers have MFIs more suitable for many applications and also have somewhat broader MMDs. Molecular mass control is a problem with the Phillips process, since it is not possible to use a chain-transfer agent such as hydrogen, which is oxidized to water by the chromate groups and acts as a catalyst poison. Molecular mass control is therefore effected mainly by the choice and treatment of the support. The use of titanium compounds is believed to result in the chromium atoms being bound to the support via titanate bonds [65]. A further parameter available for modifying the surface characteristics is treatment with fluorine compounds which convert surface hydroxyl groups to fluoride and reduce the surface area. To some extent the effect is similar to high temperature calcination [65], [66].

Catalyst productivities are of the order of 5 kg PE per gram of catalyst [63] or higher, with a corresponding chromium content of 2 ppm or less. The percentage of chromium atoms which form active polymerization centers has been estimated as 12 % [67]. With a number-average chain length of the order of 1000 monomer units, each chromium atom thus produces about 1000 molecules. The chains are terminated by a β-hydrogen shift reaction:

forming an unsaturated molecule and an ethyl ligand attached to the chromium atom [66].

The primary form of molecular mass (and hence MFI) control is by selection of a catalyst which favors the hydrogen shift reaction, but fine adjustments can be made by varying the reaction temperature, since a higher temperature favors the shift reaction.

There have been two developments of chromium catalysts by UCC which fall conceptually in the field of Phillips catalysts. CARRICK et al. reported that bis(triphenylsilyl) chromate, which is closely related to the proposed active site of a Phillips catalyst, polymerizes ethylene at high pressure [69]. When supported on silica it forms a very active catalyst for low-pressure polymerization [70]. The second type of catalyst is formed by the reaction of chromium compounds having π-bonded ligands with the hydroxyl groups on silica [16], [17], [71], [72]. Paricularly favored is dicyclopentadienyl chromium (chromacene). Unlike the Phillips catalyst it is believed that the chromium is attached to the support by only one bond, with one bond remaining to a cyclopentadienyl group. A very useful feature of these catalysts is their sensitivity to hydrogen, which allows a wide range of molecular masses to be produced. The MMD produced is fairly narrow, but not as narrow as that from some of UCC's Ziegler catalysts.

Somewhat similar to the Phillips catalyst is the Standard Oil (Indiana) catalyst which was the first of the coordination catalysts to be discovered [73]. It typically consists of MoO_3 supported on alumina or silica and calcined in air at high temperature. Unlike the Phillips catalyst it is necessary to reduce the precursor with hydrogen at elevated temperature before using in the polymerization reactor. Despite extensive development it has not been widely commercialized.

1.3.2.2. *Ziegler Catalysts*

The range of catalysts which function by the Ziegler mechanism is extremely broad and it would be impossible to cover all the variants here. However, those catalysts which meet the requirements of modern polyethylene processes are more restricted in number and tend to follow a common pattern. Some of the developments in Ziegler catalysts for polyethylene have arisen out of developments for polypropylene (see Section Historical Survey), but since ethylene has a higher reactivity and the extra parameter of stereoregularity does not have to be dealt with, the requirements of the polyethylene catalysts have generally been met more easily.

Early Ziegler catalysts for ethylene were based on β-$TiCl_3$, produced by reducing $TiCl_4$ with $AlEt_2Cl$ or $Al_2Et_3Cl_3$ at low temperature. As cocatalyst, $AlEt_3$ was used. The $TiCl_3$ produced in this way contains $\frac{1}{3}$ mole of cocrystallized $AlCl_3$. Although the catalyst productivities were much higher than for propene, it was necessary to extract the catalyst residues in order to reduce the quantities of Ti and Cl in the product to acceptable levels. Later, by the use of longer chain aluminum alkyls as cocatalyst and alkoxytitanium chlorides as transition metal compound [74], [75], the catalyst productivity was improved sufficiently to allow the costly residue removal stages to be eliminated.

Kinetic studies have shown [17], [67] that only a small proportion of the titanium atoms in $TiCl_3$ catalysts form active centers (typically < 1 %). This is believed to be due to the fact that, even with the small polymerizing particles, only a small fraction of the titanium atoms are at the crystallite surface. In order to make a higher proportion of the titanium atoms available to form active centers, various developments were made to support the transition metal compound on a carrier. Early attempts to support $TiCl_4$ directly onto silica, alumina, or magnesia did not lead to a sufficient increase in productivity [74]. The first useful high-yield catalyst used Mg(OH)Cl as support [76]. Since then a variety of magnesium compounds have been used successfully as supports [17], [74], but preeminent amongst these is $MgCl_2$ or reaction mixtures which can produce this compound, at least on the support surface. Most modern Ziegler processes seem to use catalysts which fall into this category. The massive increase in activity of $MgCl_2$ supported catalysts has been claimed to be due to an increase in the percentage of titanium atoms forming active centers (approaching 100 %) and not to a significant increase in reaction rate at the active center [16], [67]. The $MgCl_2$ supported catalysts produce polyethylenes with narrower MMDs than unsupported catalysts [16] and a narrower distribution of composition in the case of LLDPEs. As with polypropylene, electron donors such as esters or THF may be employed to modify the characteristics of the $MgCl_2$ based catalysts [16], but are not invariably used in the case of polyethylene.

For some processes, particularly the fluidized-bed and loop reactors, the catalyst shape and size is very important, and procedures such as ball-milling and chemical reaction used to produce the basic catalysts do not lead to particle sizes and shapes suitable for direct use. Further processing is required to produce a defined particle size range. Spray-drying can be used to produce spherical paricles. UCC have filed patents on the use of the microspheroidal silicas used in the Phillips process for supporting $MgCl_2$ – $TiCl_4$ systems for their gas-phase process [77]. For solution processes, as small a particle size as possible is desirable, and this may be achieved either by the method of catalyst preparation [78] or by prepolymerization treatment with a higher olefin [79].

The molecular mass of polyethylene is normally controlled by the use of hydrogen. With Ziegler catalysts at 70 – 100 °C this can require 20 mol % hydrogen in the gaseous phase of a slurry process or a gas-phase process. When other olefins are copolymerized with ethylene the concentration of hydrogen required is lower, due to chain transfer to the comonomer. At the high temperatures employed in the high-pressure process, the hydrogen concentrations used are much lower due to a relative acceleration of the rate of chain transfer to hydrogen and also a greater proportion of chain transfer by the β-shift reaction. Chain transfer to monomer or comonomer by the β-shift reaction results in unsaturation, primarily in the form of vinyl groups, but hydrogen chain transfer forms methyl-terminated chains.

1.3.2.3. *Single-Site Catalysts (Metallocenes)*

Typical Phillips or Ziegler catalysts do not follow classical polymerization kinetics and the resulting MMDs are substantially broader than the simple statistical case (see Section Coordination Catalysis). For homopolymers this is probably an advantage and gives rise to the good processing characteristics of HDPE. In the case of copolymers this type of kinetic behavior leads to a broad distribution of composition, in which some chains have low comonomer concentrations and others high concentrations. For LLDPE there are advantages such as higher stiffness than LDPE of the same density, but disadvantages of higher extractable fractions and stickiness in the lower density versions. A catalyst which could produce a narrow composition distribution would overcome these disadvantages, and at the same time less of the expensive comonomer would be required for a given density reduction.

Catalysts which behave in a uniform manner to produce simple statistical distributions of molecular mass and composition have been known for many years, but they are low-yield systems and have not been commercialized for polyethylene [80]. Such catalysts, made from vanadium oxide trichloride [80] and bis(cyclopentadienyl)titanium dichloride [81], remain soluble in the presence of the cocatalyst.

In 1983 KAMINSKY described a catalyst which combined ideal MMD and composition distribution with high yield [82], [83]. A basic form of the catalyst was bis (cyclopentadienyl)dimethylzirconium with a massive excess of methyl aluminoxane $(CH_3 – Al – O)_n$ as cocatalyst. Al/Zr ratios as high as 10 000 or more are typically employed. Since then there has been intensive development in academia and industry with the objectives of improving the thermal stability of such catalysts, reducing the concentration of cocatalyst, and, above all, making supported versions.

Because the original catalysts were bis(cyclopentadienyl) transition metal compounds, known as metallocenes, there is a tendency to refer to these recent developments as “metallocene catalysts”, but a more general term is “single-site catalysts”. Given that metallocenes had previously been investigated as catalysts with conventional alkylaluminum compounds as cocatalysts [84], it could be said that the key discovery was the use of methyl aluminoxane (MAO) as cocatalyst. The latter is made by controlled hydrolysis of trimethylaluminum and has a rather ill-defined structure. To avoid too rapid a reaction leading to aluminum hydroxide and unreacted trimethyl, SINN et al. initially used the water of crystallization of materials such as copper(II) sulfate pentahydrate as the source of water [85]. Later developments have led to physical methods for the controlled hydrolysis and the material is commercially available.

Since the transition metal components of the catalysts are stable entities with well-defined structures, investigators have been able to make systematic changes to the structure and achieve the sort of control over the polymerization process which had been hoped for in the early days of Ziegler catalysis. Principal achievements include stereospecific polymerization (see Chapter Polypropylene), higher reactivity towards other olefins and also towards other monomers not industrially polymerizable by Ziegler catalysis. It is generally accepted that the active catalytic species is a transition metal cation associated with an aluminoxane counteranion [19], [20]. Some investigators believe that the function of the MAO is to act as a source of free trimethylaluminum and also to act as a receptor of the anion produced by the reaction between the catalyst and cocatalyst [86], [87]. Polymerization proceeds more rapidly in aromatic solvents and even more rapidly in chlorinated aromatic solvents, and this supports the view that a higher dielectric constant aids the formation of an optimal ion pair [87]:

Both metallocene dichlorides and dimethyl forms of the catalysts are frequently described, but MAO transforms the former into methyl-substituted species. Chemical changes have been generally directed to modifying the stereochemical environment of the active center and include changes such as replacing the cyclopentadienyl groups with indenyl or fluorenyl, alkyl substitution of the cyclopentadienyl rings, and linking two indenyl units to form a more rigid cage. Alkyl substituents can have a major effect on the catalyst activity [88]. Single-site catalysts have also been made which have only one cyclopentadienyl ligand [89]. Some general forms of single-site catalysts include:

The active sites are tetrahedrally coordinated, in contrast to heterogeneous Ziegler catalysts which are octahedrally coordinated in a $TiCl_3$ or $MgCl_2$ crystal lattice. In principle the greater openness of the tetrahedral configuration allows more ready access to bulkier monomers than the octahedral structure, but the ligands themselves are generally rather large. The improved incorporation of monomers larger than ethylene is generally only achieved by bridged systems, in which the opening angle can be greater than the 109° of a regular tetrahedron. Dow refer to their catalysts as “constrained geometry” catalysts and specify that they reduce the bond angles of the coordinated ligands to less than 109°, so that a greater solid angle is available for the entry of monomers to the free coordination site [90].

Developments in cocatalysts have been directed to reducing the ratio of cocatalyst to transition metal and developing better defined chemical entities as cocatalysts. Montell have shown that highly active aluminoxanes can be formed from trialkylaluminum compounds other than the methyl derivative, and that in some cases they are even more active than MAO [91]. When made from higher molar mass aluminum alkyls, well-defined cocatalyst compounds such as tetraalkyldialuminoxanes can be isolated.

The large excess of MAO found to be necessary to obtain optimum activity in many studies on metallocene catalysts may be due in part to moderately high molar concentration of the cocatalyst needed to generate the active centers. When catalyst and cocatalyst are precontacted at high concentrations and then diluted for polymerization, Al/Zr ratios as low as 20 can be effective [92]. Apart from aluminum-based cocatalysts, boron compounds have been used and allow much lower cocatalyst/catalyst molar ratios to be achieved [93]:

The general aspects of ethylene polymerization with metallocene catalysts are similar to those of Ziegler catalysis: molecular mass control can be effected by chain transfer to hydrogen; at higher temperatures chain transfer by the β-shift reaction produces vinyl groups; metallocene catalysts tend to be thermally labile and decompose to inactive species [87].

Industrially, the fact that the original metallocene catalysts were soluble meant that the immediate applications were in solution processes. Exxon took the view that the catalysts were short-lived and expensive and developed a high-pressure process to give a high catalyst yield [94], [95]. Product targets were VLDPEs with a lower content of extractables and less tackiness. Dow, which operates a solution process for HDPE and LLDPE, has developed high-temperature catalysts for producing a range of homopolymers and copolymers. They claim improved processability for these products due to incorporation of long branches by copolymerization of vinyl end groups of polymer chains formed by β-scission [90]. The solution process favors end-group polymerization because the high temperature leads to formation of a high proportion of chain ends by β-scission; the polymer to monomer concentration ratio is high; and the catalyst is chosen to readily incorporate higher molecular mass olefin monomers. Other routes to improve the processability of the product include the use of mixed catalysts with different molar mass dependence on hydrogen concentration or temperature [96], [97].

For use in fluidized bed or slurry phase reactors, a supported catalyst is required. This has been achieved by many companies by treating a silica having the required particle size with MAO and then with the metallocene catalyst. The characteristics of narrow MMD etc. are maintained. In 1996 most major manufacturers are developing single-site catalyzed PEs, but the amount actually being sold is a very small fraction of PE sales. However, the catalysts can be used in all the major PE processes now using Phillips and Ziegler catalysts, and a changeover to single-site catalysts could occur comparatively quickly, depending on the advantages and disadvantages the new products present to plastics fabricators and end-users.

1.3.2.4. *Copolymerization*

Copolymerization of ethylene and α-olefins is the basis of the large and expanding LLDPE market. As with the free radical case the important factors in addition to those of homopolymerization are the relative reactivities and chain transfer. Both Phillips and Ziegler catalysts copolymerize olefins, but the latter are more widely used because they can be more readily tailored to produce narrow distributions of composition and molecular mass. As has been noted in Section Coordination Catalysis, polymerizations with typical coordination catalysts do not follow classical polymerization kinetics and hence the reactivity ratio concept is not strictly applicable. For completely soluble polymerization systems r_1 is very high and increases with the comonomer chain length (e.g., 29 for butene and 73 for octene, calculated from data in [41]). However, in the case of heterogeneous catalysts and heterogeneous polymerization systems, in particular, the apparent reactivity ratios are lower and may even decrease with increasing olefin chain length. This is presumably due to mass transfer and solubility effects in the growing particles. Chain transfer is enhanced in the presence of olefin comonomer, but this can be compensated by lowering the hydrogen concentration.

Literature articles have appeared on the copolymerization of ethylene with monomers such as styrene, butadiene, vinyl chloride, esters, and others but these have involved Ziegler catalyst variants with poor yields. For practical purposes the range of comonomers polymerizable by Ziegler catalysis is at present limited to olefins and nonconjugated diolefins. The advent of single-site catalysts with high intrinsic activity is removing some of these limitations.

1.4. Raw Materials

1.4.1. *Ethylene*

The first polyethylene plant built by ICI used ethylene produced by dehydration of ethanol. Modern ethylene production plants are based on the thermal cracking of

hydrocarbon feedstocks at ca. 850 °C. Due to the availability of raw materials, the feedstock used predominantly in North America was originally ethane, with naphtha being used more commonly in Europe. The tendency now is for crackers to be designed to accept a wider range of feedstocks, so as to match the range of coproducts such as propene to the market requirements.

Modern plants produce ethylene with a quality which in many cases is suitable for polymerization with little or no further purification. In North America and Europe, producers supply ethylene to an agreed specification via a common ethylene grid, and polymerization plants take their supplies from these pipelines. In the case of sensitive catalyst systems such as the Phillips catalyst some further purification may be necessary to ensure that maximum impurity levels are not exceeded. Table 8 lists specifications for a polymerization-grade ethylene suitable for most processes. There are overall limits on inert materials such as ethane or nitrogen which, because of the efficient recycle system, could build up and dilute the process stream. The main impurities of importance to the free-radical process are oxygen and water. The former could cause inhibition of low-temperature initiators, or uncontrolled initiation of reaction at higher temperatures. At moderate concentrations (after concentration by the recycle) water can form ethylene hydrate [98] in the cooler parts of the high-pressure process, completely blocking the pipework. Some of the other specified compounds can produce problems of molecular mass control or inhibition in the free-radical process, but only at very much higher concentrations.

Table 8. Specifications for polymerization-grade ethylene *

C_2H_4	> 99.9 vol %
CH_4, C_2H_6, N_2	< 1000 vol ppm
Olefins + diolefins	< 10 vol ppm
Acetylene	< 2 vol ppm
H_2	< 5 vol ppm
CO	< 1 vol ppm
CO_2	< 1 vol ppm
O_2	< 5 vol ppm
Alcohols (as MeOH)	< 1 vol ppm
H_2O	< 2.5 vol ppm
Sulfur	< 1 vol ppm
Carbonyl sulfide	< 1 vol ppm

* Data obtained from Repsol.

In the case of the Phillips and Ziegler processes, the materials included in the specification act as catalyst poisons. Hydrogen is a poison only for the Phillips catalyst.

1.4.2. *Comonomers*

The vinyl acetate and acrylate esters used as comonomers in the free-radical process are normal commercial quality materials containing sufficient stabilizer to prevent homopolymerization in storage or during pumping, but not so much as to affect the copolymerization reaction. They must be freed of dissolved oxygen by nitrogen sparging.

The butene used in LLDPE is normally a purified refinery product, although in the United States material is available from the oligomerization of ethylene. As an alternative to buying butene with its associated transport problems, IFP have developed the Alphabutol process [99], [100] for dimerizing ethylene as a compact adjunct to a polymerization plant. There is also the possibility of using a polymerization catalyst capable of simultaneously dimerizing ethylene [101], [102].

The higher α-olefins such as hexene and octene used in LLDPE processes are ethylene oligomerization products. They must be freed of oxygen and water before use in the polymerization process. The 4-methylpentene used by BP is a propylene dimer made by an alkali metal catalyzed process.

1.4.3. *Other Materials*

The initiators and catalysts are described in Section Free-Radical Catalysis. All the free radical initiators and many of the Ziegler and Phillips catalysts are manufactured by specialist suppliers. Some of the simpler Ziegler catalysts may be made on-site from basic chemicals such as $TiCl_4$, $MgCl_2$, etc. The aluminum alkyls are made by a very few international suppliers.

Initiator solvents and compressor lubricants for the free-radical process are carefully selected to be free of aromatic compounds, since much of the product may be used for food packaging.

1.5. Production Processes

Modern polyethylene production processes offer the possibility of a versatile range of products. High-pressure processes can produce LLDPE in addition to the normal range of LDPEs and ester copolymers. As well as HDPE some low-pressure plants can also produce LLDPE and VLDPE, and in many cases these compete for the same market as LDPE and the ester copolymers. A guide to the applicability of the various types of processes is given in Table 9.

Table 9. The technical applicability of processes for polyethylene manufacture *

	High-pressure autoclave	High-pressure tubular	Gas-phase fluidized bed	Slurry phase autoclave/loop	Solution autoclave
Installed capacity ** worldwide, 10^6 t/a	8.8	8.3	12.8	12.5	3.2
LDPE	+	+	–	–	–
EVA copolymers	+	+	–	–	–
Acrylate copolymers	+	+	–	–	–

UHMPE	–	–	0	+	–
LLDPE	+	0	+	0	+
VLDPE	+	0	+	–	+

* + = suitable; 0 = technically feasible with some limitations; – = unsuitable or not possible.
** Capacity data (1995) obtained from Chem Systems, London.

Table 10 compares the capital and operating costs for various types of polyethylene plant. The comparison is on the basis of construction on a United States Gulf Coast site using the largest stream size currently (1996) available for licensing. The costings assume the production of pellets and this results in higher costs for the gas-phase and slurry plants than would be the case if 100 % sales of ex-reactor granules could be assumed. Some differences due to the economy of scale occur as a result of the available stream size. The production costs are dominated by the cost of ethylene, although some differences such as the extra cost of electrical energy can be noted. In the case of LLDPE these costings assume a unit cost for the butene equal to 1.05 times that of ethylene. In many other parts of the world the price of butene, including transport, is considerably higher. The unit price of higher olefins is generally appreciably higher than that of ethylene, from which they are derived by oligomerization.

Table 10. Production costs for polyethylene processes in $/t (1996 U.S. Gulf Coast prices) *

Product	LDPE	LLDPE	HDPE
Process	Autoclave Tubular	Fluid bed Solution	Fluid bed Ziegler Phillips

Capacity, 10^3 t/a	117	200	225	200	200	200	200
Capital cost, 10^6 $	85	116	98	138	90	135	105

Total costs	636	603	578	630	577	620	592

* Data from Chem Systems, London.
** Includes cost of butene monomer at a unit price equal to1.05 times that of ethylene; other locations or the use of other olefin comonomers could lead to a higher monomer cost.

1.5.1. *High-Pressure Process*

A flowsheet of the high-pressure polyethylene process is shown in Figure 14. The reactor may take one of two forms: a high-pressure autoclave or a jacketted tube, but otherwise the processes are similar. The reaction pressure is typically in the range 150 – 200 MPa for the autoclave process and 200 – 350 MPa for a tubular reactor. Such high pressures call for very specialized technology and many key features have remained proprietary information. The design of thick-walled cylinders requires a different type of analysis [103], [104] from that for lower pressure vessels, and fatigue is a major design consideration for pumps and compressors. A drawing of the second stage cylinder of a high-pressure ethylene compressor is shown in Figure 15, which illustrates the massive construction necessary and the avoidance of cross-bores to improve fatigue resistance at the very highest pressures. Specialized forms of sealing joints in vessels and pipework have been developed which make use of the pressure itself to increase the sealing forces [105].

Figure 14. High-pressure autoclave process

Figure 15. Second stage cylinder of a Nuovo Pignone compressor with 350 MPa maximum output pressure

a) Piston; b) Packings; c) Lubricant injection to packings; d) Valves

Referring to Figure 14, the fresh ethylene enters from the refinery at ca. 5 MPa, mixes with the low-pressure recycle and is compressed to 25 MPa. After mixing with the intermediate-pressure recycle, the pressure is raised in the secondary (or hyper) compressor to 150 – 350 MPa for feeding to the reactor. The pressure in the reactor is controlled automatically by a flow control valve at the reactor outlet. The reaction mixture then passes through a cooler to reduce the polymer temperature to a value suitable for feeding the pelletizing extruder. The polyethylene is separated from the majority of the unreacted monomer in the intermediate separator at ca. 27 MPa. This pressure is chosen to give a compromise between separation efficiency and compression energy savings. The remaining monomer is removed in the low-pressure separator that feeds the pelletizing extruder. The extrudate is pelletized underwater by a die-face cutter, and the pellets are then dried and conveyed to temporary storage hoppers to await quality control clearance. Finally the pellets are transferred to silos for blending and storage, before off-loading to tankers or sacks.

1.5.1.1. *Autoclave Reactor*

A typical autoclave design is shown in Figure 16. The autoclave volume is chosen to give an overall residence time of ca. 30 – 60 s, with corresponding volumes in larger plants of ≥ 1 m^3. A novel feature is the internal stirrer motor. The Du Pont process uses an external motor. The elongated cylindrical form arises partly from the fabrication constraints of making a thick-walled forging, and partly from the requirements of the process for multiple zones. Cross-bores are provided along the length of the reactor for thermocouples, and monomer and initiator entries. Bursting disks or other relief devices are mounted directly into the reactor walls to provide unrestricted passage for the reactor contents in the event of a pressure rise due to a decomposition.

Figure 16. High-pressure autoclave reactor

a) Stirrer motor; b) Stirrer shaft; c) Bursting disk ports

The autoclave functions as an adiabatic continuous stirred-tank reactor (CSTR), with the heat of reaction being removed by the fresh ethylene entering the reactor. The conversion of monomer to polymer is thus related to the difference in temperature between the feed gas and the final reaction temperature. For practical purposes percentage conversion = 0.075× ΔT. Most modern reactors have two or more zones with increasing temperatures. The reaction temperatures are maintained constant by controlling the speeds of the pumps feeding initiators into the respective zones. The first zone is typically 180 °C and the final zone 290 °C. For adequate control the initiators must have decomposition half-lifes of ca. 1 s under the reaction conditions in the zone. Table 6 lists a range of commercial initiators used in both the autoclave and tubular processes.

1.5.1.2. *Tubular Reactor*

A tubular reactor typically consists of several hundred meters of jacketted high-pressure tubing arranged as a series of straight sections connected by 180° bends. Inner diameters of 25 – 75 mm have been quoted, but 60 mm or somewhat larger is probably typical of modern tubular reactors. A ratio of outer to inner diameters of about 2.5 is used to provide the necessary strength for the high pressures involved. At many of the pipe junctions thermocouples are introduced to follow the course of the reaction, and initiator and gas inlets or pressure relief devices may also be incorporated. Unlike the autoclave process, no after-cooler is required for the secondary compressor, but the first section of the tubular reactor must function as a preheater to raise the ethylene to a sufficiently high temperature for the reaction to start. This temperature depends on the initiator employed, ranging from 190 °C for oxygen to 140 °C for a peroxydicarbonate. The latter part of the reactor functions as a product cooler similar to that of the autoclave process.

A tubular reactor works in the plug flow regime with heat transfer to the jacket. Plug flow is achieved by the correct choice of pipe diameter relative to the flow rate [106] so as to give sufficient turbulence and good axial mixing. Although heat is transferred through the reactor wall, it is not generally possible to maintain isothermal conditions, and temperature peaks occur. Because of the temperature peaks, which may not occur at exactly constant position in the tube, automatic temperature control must be more sophisticated than in the autoclave process; i.e., it must be possible to calculate average temperatures for appropriate regions of the reactor. When oxygen is used as initiator, the temperature control acts on the rate of addition of oxygen in the lower pressure part of the system. When peroxide initiators are used, the speeds of the high-pressure pumps are controlled. Oxygen is still widely used in the tubular reactor process, either alone or in conjunction with peroxides. Because of its complex initiation mechanism, oxygen tends to give more gentle temperature peaks with less tendency for decomposition. In the case of reactors with multiple initiator injection, liquid initiators offer more flexibility, since they can be injected at points where there is no fresh ethylene injection (which would be required to carry in oxygen as initiator). Injection of initiator at various positions along the tube produces new temperature peaks, increasing the overall conversion. By using these techniques higher conversions than in the autoclave reactor can be achieved, but at a higher cost in compression energy. Although conversions of up to 35 % (compared with 20 % for the autoclave) have been claimed, the maximum useful conversion depends on the product quality required, since quality deteriorates markedly with increasing conversion.

1.5.1.3. *High-Pressure Copolymers*

The high-pressure processes described are also suitable for the copolymerization of monomers such as vinyl acetate or acrylic esters. The autoclave process is generally

preferred for its well-defined operating conditions and its ability to produce a useful conversion at a low maximum temperature. In the case of vinyl acetate the reactivities of the two monomers are virtually identical and so they are consumed at the same rate. This means that the reacting monomer mixture and the copolymer produced maintain a constant composition even in multizoned reactors, but the recycle system must handle high concentrations of vinyl acetate. The converse is the case for the acrylate esters. If a multizoned or a tubular reactor is used the composition varies in the different zones, but the recycle is nearly pure ethylene. The principal modifications to a high-pressure polyethylene plant to enable it to manufacture copolymers are:

1. Installation of liquid pumps, which usually pump the comonomer into the suction of the secondary compressor
2. In the case of vinyl acetate, it is necessary to collect the monomer which condenses in the low-pressure recycle system and purify it before returning it to the liquid pump
3. The system for removing final traces of monomer must be improved, because the comonomers are more soluble than ethylene and they have more offensive odors

Technically a copolymer plant could also copolymerize acrylic or methacrylic acid, but there are long-term corrosion problems. Major producers of these copolymers have constructed plants especially for their manufacture, using corrosion-resistant steels.

1.5.1.4. *Linear Low-Density Polyethylene (LLDPE)*

CdF Chimie converted high-pressure process equipment to use Ziegler catalysts to make HDPE. These plants were later used to copolymerize ethylene with butene and other comonomers to make LLDPE. The catalysts used are generally of the Ziegler type but have been specially developed for the high temperatures of the high-pressure process [107]. Several other manufacturers have modified existing high-pressure plants to enable them to make a rapid, but limited entry into the LLDPE market, but this route is not seen as suitable for a large new investment. The required modifications (generally similar to those for free-radical co-polymers together with some additional ones associated with the different type of catalyst) are as follows:

1. Purification columns to remove polar impurities from the ethylene and olefin comonomer.
2. Hydrogen injection for MFI control.
3. Compressor modifications to take account of the lower compressibility and poorer lubricating properties of the monomer mixture [108]. The concentrations of butene or other olefin of ca. 50 % are much higher than in the free-radical copolymer case.
4. Catalyst handling equipment to produce pumpable dispersions, and to maintain the catalyst under a nitrogen atmosphere.
5. A system for injecting a catalyst deactivator such as a suspension of calcium stearate [109], after the reactor and before the separator.
6. Usually some modifications to the pelletizing extruder to take account of the higher torque generated by LLDPE.

1.5.2. *Suspension (Slurry) Process*

The formation of polyethylene suspended in a hydrocarbon diluent was envisaged as a convenient form of production process from the earliest patenting by ZIEGLER [110]. This was reinforced by the fact that, for a given pressure, most Ziegler catalysts give their highest yields at temperatures at which polyethylene is insoluble. The Phillips process on the other hand originated in the laboratory as a solution process that uses a fixed bed of catalyst [111] and was commercialized in 1956 as a solution process using a powdered catalyst which had to be removed by filtration. Laboratory developments led to the discovery of high-activity catalysts which fragment at temperatures below 105 °C to enable the low concentration of finely divided catalyst residues to be left in the product. Since 1961 all Phillips plants have been of this type using novel process technology to implement their Particle Form suspension process.

Many companies have built plants to make polyethylene by using Ziegler catalysts, but because the license was only for the use of the catalyst, there has been a diversity of process designs, even amongst the suspension processes. The Phillips process was licensed as a package and the plants themselves tended to be very similar. More recently the picture has become blurred as chromium-based catalysts have been used in fluidized-bed reactors and Ziegler catalysts are being employed in loop reactors. Early Ziegler plants included a catalyst residue removal stage which added considerably to the complexity and cost. Since the late 1960s it has been possible to eliminate this step. Other variations arise from the selection of the diluent. A high-boiling diluent generally requires more energy to remove the final traces from the polymer, and stripping with steam is frequently employed. Because of the low flash point, the use of a low-boiling diluent such as hexane requires more care in the design and operation of the plant, but this seems to be the preferred route for modern plants.

The suspension process has been used extensively for the production of HDPE, and in many cases these polymers incorporate a small amount of comonomer to increase the toughness or resistance to stress cracking. The use of higher concentrations of comonomer to produce LLDPE presents problems however, as a significant fraction of the product dissolves in the diluent. Because of the poorer solvent properties of isobutane, the Phillips process is best suited to making lower density materials. With the original Phillips catalysts the lower density limit was considered to be about 930 kg/m^3, but with more recent catalysts, particularly supported single-site catalysts, the limit is reduced to around 920 kg/m^3.

1.5.2.1. *Autoclave Process*

Figure 17 shows a flowsheet for a suspension (slurry) process based on various descriptions of the Hoechst process [8], [74], [112], [113]. The pressure employed is between 0.5 and 1.0 MPa, allowing the use of large reactors (ca. 100 m^3). The reaction temperature is 80 – 90 °C. The diluent is a low-boiling hydrocarbon such as hexane. The catalyst compounds and aluminum alkyl are slurried with diluent in the catalyst mixing vessel before being fed to the reactor at a rate sufficient to maintain the required polymerization rate. Only one main reactor is shown but, at least in the case of bimodal MMD high molecular mass polymers [114], two or more reactors in cascade may be used. The reaction mixture is then passed to a run-down reactor where the dissolved ethylene is consumed almost completely, avoiding the need for an ethylene recycle. The slurry concentration is an important parameter in the process. A high concentration allows higher outputs from a given reactor volume, but the heat transfer to the cooling jacket is worse and stirring becomes more difficult. The maximum usable slurry concentration depends on a number of factors, including solvent type, particle size and shape, but principally on the bulk density of the polymer particles. Slurry concentrations vary from 15 to 45 wt % [115], with many patents reporting values in the range 30 –35 % in a heavy diluent.

Figure 17. Hoechst suspension polymerization process

a) Catalyst preparation vessel; b) Polymerization reactor; c) Run-down reactor; d) Centrifuge; e) Fluidized-bed drier; f) Diluent condenser; g) Nitrogen circulator; h) Powder-fed extruder

The slurry from the run-down reactor then passes to a centrifuge to remove the bulk of the diluent, which is recycled directly to the reactor. This diluent contains aluminum alkyl and comonomer, if used, and the injection rates of these raw materials are adjusted to take into account the amounts reintroduced by the diluent recycle. The polymer is dried in a continuous fluidized-bed drier in a stream of hot nitrogen to remove residual diluent. Further quantities of diluent are condensed from the circulating nitrogen stream and recycled. Before extrusion into pellets, stabilizers are added to neutralize the catalyst residues, and other additives such as antioxidants may be added at this point.

The powder-fed extruder has a longer barrel than is the case for the high-pressure process because in addition to generating sufficient pressure for the pelletizing head, it must also melt the polymer powder. Although a single long barreled extruder is shown, new installations increasingly make use of a combination of a short extruder to melt the polymer followed by a gear pump to generate the pelletizing pressure. This combination has a lower energy requirement.

1.5.2.2. *Loop Reactor Process*

A simplified flowsheet for the Phillips Particle Form process is shown in Figure 18. The novel double loop reactor constructed from wide-bore jacketted pipe was developed by Phillips engineers to avoid deposits, which had been troublesome in a stirred autoclave [111], [116]. It also has a high surface-to-volume ratio, facilitating heat removal and allowing short residence times. The impeller forces the reaction mixture through the pipework in a turbulent regime with a velocity of 5 – 10 m/s. The reaction conditions of 100 °C and 3 – 4 MPa correspond to the needs of the chromium-based Phillips catalyst and the required productivity. The diluent used is isobutane which facilitates the subsequent flash separation and, being a poor solvent for polyethylene, permits higher operating temperatures than the higher alkanes. The catalyst is flushed into the reactor with diluent from the metering device at the base of the catalyst slurry tank. The polymer is taken off from a sedimentation leg which enables the slurry to be passed to the flash tank at a concentration of 55 – 65 % instead of the 30 – 35 % circulating in the loop reactor [111]. The isobutane diluent evaporates in the flash tank and is then condensed and recycled. Residual isobutane is removed in a nitrogen-flushed conveyor. Pelletization is carried out in a powder-fed extruder in a similar way to the Hoechst process.

1.5.3. *Gas-Phase Process*

Fluidized-bed processes for the production of HDPE were developed in the late 1960s by Union Carbide and somewhat later by Naftachemie (now BP). Although an innovative technology, the process did not offer clear economic advantages over the established slurry processes (see Table 10). A rapid increase in the building of fluidized-bed plants followed Union Carbide's announcement of their Unipol process for LLDPE in 1977. In this case the fluidized-bed process is competing with solution and high-pressure processes compared to which it has lower capital and operating costs, particularly if it can be assumed that customers are able to use ex-reactor granules directly (not assumed in Table 10). Many fluidized-bed units have been built as dual-purpose plants ("swing plants") with the ability to produce either LLDPE or HDPE according to demand. The fluidized-bed process can produce a very wide range of MFIs and densities since it is free of the viscosity constraints of the solution process and the solubility constraints of the slurry process. Ranges of < 0.01 to > 100 in MFI and densities from 890 to 970 kg/m^3 have been claimed [117], [118]. Originally the process used butene as the comonomer for LLDPEs, but later hexene was introduced for high-performance copolymers. BP uses 4-methylpentene for its high-performance LLDPEs.

Figure 19 shows a flowsheet for the Union Carbide fluidized-bed process [119]. The reactor has a characteristic shape with a cylindrical reaction section, and an expanded section in which the gas velocity is reduced to allow entrained particles to fall back into the bed. The bed diameter is ca. 4 m with a working height of 10 m and an overall height of the reaction unit of ca. 30 m. The gas enters the reactor through a distributor plate which provides an even distribution of gas and must also prevent powder falling through when the gas flow is stopped. The fluidized bed functions more or less as a continuous stirred-tank reactor in which mass transfer provides back mixing of material and heat throughout the reactor. There is a predominant upflow at the center and downflow at the walls. Reaction temperature is 80 – 100 °C, depending on the density of the product being made, and the pressure is in the range of 0.7 – 2.0 MPa. Originally, lower pressures were used for butene and hexene to avoid condensation in the recycle cooler, but it is now claimed that condensation can be used to increase the output since the heat of vaporization of the liquid olefin absorbs more heat from the polymerizing particles [120]. The conversion per pass is ca. 2 % for HDPE, but higher when using an olefin comonomer in the condensing mode. The positioning of the catalyst feed point and the polymer offtake is important to minimize the loss of catalyst particles, which results in low conversion. A cyclone and/or filter prevent fine particles reaching the recycle cooler and compressor. The polymer is removed via a sequenced valve to a powder cyclone, from which residual monomers are recovered and recompressed. The main recycle compressor circulates gas at a high flow rate, but with a small pressure rise. Since the process operates close to the melting point of the polymer, accurate temperature control is necessary by regulating the rate of catalyst addition. If a runaway reaction is detected, a gas such as carbon dioxide can be injected to poison the catalyst.

Figure 19. Fluidized-bed process

a) Catalyst hopper and feed valve; b) Fluidized-bed reactor; c) Cyclone; d) Filter; e) Polymer take-off system; f) Product recovery cyclone; g) Monomer recovery compressor; h) Purge hopper; i) Recycle compressor; j) Recycle gas cooler

The selection of the catalyst is critical for the success of the process. The catalyst particle grows by a process of replication to about 15 – 20 times its initial size. Not only does this affect the fluidization characteristics, but the polymerization rate and heat transfer must be controlled to prevent fusion of the particles or a thermal runaway reaction. Catalysts based on microspheroidal silica or $MgCl_2$ with a mean particle size of about 50 µm are claimed to be particularly suitable [77].

1.5.4. *Solution Process*

Solution processes have been developed by various companies including Du Pont, Dow, DSM, and Mitsui for the manufacture of LLDPE or HDPE/LLDPE on a swing basis. The advantages are that they readily handle a wide range of comonomer types and product densities and, depending on catalyst type, tend to produce narrow MMD products more readily. Like the high-pressure process (which is also a solution process) they are unable to handle high-viscosity products. The Du Pont and DSM processes are similar to the high-pressure process in that they function adiabatically with short residence times, whereas the Dow and Mitsui processes remove heat from the reaction mixture. Since the Du Pont process is available under license and more plants of this type have been constructed, this is the process included in the table of cost estimates (Table 10) and described below. The Du Pont process has a catalyst residue removal stage and for this reason is probably not the most economic solution process.

Figure 20 shows a flowsheet of the Sclairtech process of Du Pont of Canada [121]. The ethylene is dissolved in a diluent such as cyclohexane and pumped to the reactor at ca. 10 MPa. The reaction step is adiabatic and the reaction temperature is in the range 200 – 300 °C. The feed contains ca. 25 wt % ethylene, of which 95 % is converted to poylethylene in the reactor. The residence time is ca. 2 min. The catalyst most frequently quoted in patents is a mixture of $VOCl_3$ and $TiCl_4$ activated by an aluminum alkyl. Although the catalyst components may be initially soluble, the active catalyst species appears to be heterogeneous [80]. The polyethylene solution leaving the reactor is treated with a deactivating agent and the mixture then passes through a bed of alumina where the deactivated catalyst residues are adsorbed. Two depressurization stages follow, similar to the high-pressure process, in which solvent and unreacted monomers are volatilized. After extrusion into pellets, further removal of solvent residues is achieved by passing a heated stream of gas through the bed of pellets.

1.6. Uses

Table 11 shows an analysis by end-use of approximately half of the world market for polyethylenes. The pattern is very different for the two classes. LDPE (together with LLDPE which is sold into the same market) is used predominantly for films, not all of which is for packaging. Because of its greater rigidity and better creep properties, HDPE is used in more structural applications, and also has important applications in the packaging of aggressive liquids such as bleach, detergent, and hydrocarbons. The basic techniques of plastics fabrication are treated in ⟶ Plastics, Processing and so only the aspects particular to polyethylene are discussed here.

Table 11. Consumption by application*, %

Market	HDPE	LDPE and LLDPE
Film	24	71
Blow molding	36	1
Injection molding	21	6
Extrusion coating		9
Pipe	10	2
Wire and cable insulation	1	4
Others	8	6

* Percentages based on data for Western Europe, Japan, and North America 1996 [122].

1.6.1. *Film*

LDPE retains its position as a preferred packaging material because of its limp feel, transparency, toughness, and the ability to rapidly take up the shape of the contents of the bag. Other materials such as thinner HDPE film or paper may in some cases be more economical, but are less acceptable to the customer. Most LDPE film is produced by the film blowing process (⟶) but flat film extruded onto chilled rolls (⟶) is also made, particularly in the United States. An LDPE for high-clarity film typically has a MFI of 2 and a density of 920 kg/m^3 and is extruded at 160 – 180 °C. The cast film process is usually used with higher density polyethylenes (930 – 935 kg/m^3), where the quenching on the chilled rolls enables good optical properties to be achieved with a higher film stiffness. The bubble diameter in the tubular film process may be up to 2 m for general purpose packaging, and larger for heavy gauge industrial film. Originally, bags were made directly from tubular film by welding one end, but the tendency now is to make wide film on large machines and fabricate the bags by welding and cutting. Apart from packaging film and heavy duty sacks, increasing quantities of polyethylene are used for impermeable or stabilizing membranes in civil engineering construction.

Additives play a particularly important role in the production of LDPE film by the film blowing process. Without additives, the pressure of the windup rollers on the warm film forces the surfaces into such close contact that subsequently it may be virtually impossible to separate them. High-gloss films are the worst affected. This is overcome by adding an antiblocking agent such as very fine silica, which roughens the surface on a submicroscopic scale without significantly affecting the optical properties. To reduce the friction between the surfaces a slip agent such as oleamide or erucamide is added. Other additives may be added to achieve effects in the final product such as

oxidation resistance, UV resistance, or antistatic properties.

A film extruder designed for LDPE requires extensive modifications to allow it to extrude LLDPE at comparable rates [123-125]. To avoid this investment and the lack of flexibility, many film manufacturers (particularly in Europe) use blends of LDPE and LLDPE. The equipment modifications required are:

1. The screw must have greater clearance between the flights and the barrel to avoid temperature buildup due to the higher shear viscosity. Ideally the screw should be shorter.
2. The die gap must be widened to reduce the shear rate and so avoid a type of surface defect, known as shark skin, to which narrow MMD polymers are prone. To some extent this problem can be avoided by incorporating additives based on fluoroelastomers (Du Pont, 3M) or silicones (UCC) [126-128].
3. The cooling ring must give more rapid quenching of the melt to avoid the development of excessive crystalline haze, and also to give more support to the bubble because of the lower tensile viscosity under the inflation conditions. Apart from this lack of inherent stability of the bubble, the low tensile viscosity is responsible for the major product advantage of LLDPE, since high stresses do not occur when the melt is drawn down to thin film. LLDPE can be drawn down to much thinner film without the bubble tearing than can a LDPE with equivalent mechanical properties.

HDPE film is generally made on units specifically optimized for the high molecular mass grades normally used. To produce tough films a balanced orientation of the film is necessary, and a high ratio of die diameter to bubble diameter ("blow ratio") is used so as to balance the machine direction draw with a high transverse draw. A characteristic stalk-shaped bubble is used in which substantial machine-direction draw takes place before a rapid expansion occurs some distance above the die. Mechanical guides are needed to stabilize the bubble. HDPE film is opaque and is usually used in much thinner gauges than LDPE. It competes with LDPE in areas such as carrier bags and supermarket convenience bags.

1.6.2. *Extrusion Coating*

LDPE is used extensively for coating cardboard, paper, and aluminum for milk cartons etc., for which a very low level of impurities is required. Extrusion is carried out at ca. 300 °C through a wide-slit die. Polymers with a high die swell due to long branching perform best, since the tendency to expand on leaving the die opposes the "neck-in" tendency when the melt is drawn onto the substrate. A typical LDPE used for this application has a MFI of 4 and a density of 920 kg/m^3.

1.6.3. *Blow Molding*

HDPE is now the preferred material for blow-molded containers for liquids, combining adequate environmental stress crack resistance with higher rigidity than LDPE, and hence permitting lower bottle weights for a given duty. The major uses are in the domestic market for bleach, detergents, and milk. For this application a HDPE with a MFI of 0.2 and a density of 950 g/m^3 is suitable. Other uses include a variety of industrial containers and gasoline tanks. There is a trend to higher molecular mass and to broader MMD polymers, with bimodal MMDs achieved by using catalyst or reactor developments [129].

1.6.4. *Injection Molding*

Injection molding is used for a variety of products. Some, such as caps and lids are used in the packaging field. Other applications such as housewares, toys, and industrial containers are more durable. According to whether high flexibility is required or not, LDPE or HDPE may be used. Some LLDPEs with a narrow MMD are particularly well suited for this method of fabrication. MFIs range from 2 to > 40. A narrow MMD gives the best compromise between toughness, flow into the mold, and freedom from warpage in the finished product.

1.6.5. *Pipe*

The use of polyethylene for pipes is one of the few engineering applications, where the applied stresses are carefully assessed and a lifetime of at least 50 years is required. Polyethylene is used for water and natural gas local distribution systems and, unlike many other uses, there is a substantial stress applied continuously. The potential problem is thus long-term stress rupture, and this must be carefully assessed by extrapolation and accelerated testing. Large quantities of pipe made of a medium-density polyethylene designed to withstand a stress in the PE of 8 MPa have been laid, but recent advances in bimodal HDPE polymers now enable a 50-year lifetime at a design stress of 10 MPa to be met. The first polymers which met this specification (PE 100) were introduced by Solvay in their TUB 120 range, but now all major producers have similar polymers in their ranges [130], [36].

1.6.6. *Wire and Cable Insulation*

Because of its outstanding dielectric properties, the first application of polyethylene was the insulation of very high frequency and submarine telephone cables. These have continued to be made from LDPE, but uses have expanded into telephone and power cables. In the latter case cross-linking is increasingly used to enhance the properties and allow a higher current rating for a given size of cable.

1.6.7. *Ethylene Copolymers*

The processing techniques used for copolymers are generally the same as used for polyethylene homopolymers, but the range of applications is generally more diverse [12]. The property most generally exploited is the decreased rigidity to give more flexible film, moldings, and tubing than is possible with LDPE. Copolymers with high comonomer content are generally competitive with plasticized PVC and rubbers, with a low extractable additive content as an advantage. For flexibility down to the lowest temperatures acrylate copolymers are preferred over EVA copolymers. VLDPE copolymers, particularly those made by single-site catalysts, are increasingly being used in applications requiring flexibility combined with thermal stability and good low-temperature flexibility.

Ethylene copolymers are also used in blends, in the same way as rubbers, to confer increased toughness. Particular applications include blends with wax and with bitumen for paper coating and road surfacing, respectively. Copolymers are also used as constituents of hot melt adhesives.

1.6.8. *Ultra High Modulus Polyethylene Fibers*

Because of their low softening point polyethylene fibers have not been of interest for general purpose textile use, although substantial amounts are used for producing monofilament. In 1973 Capaccio and Ward showed that solid HDPE could be drawn at elevated temperatures to very high draw ratios to produce fibers with a tensile modulus of 70 GPa and a tensile strength of 1 GPa (Kevlar 149: 172 GPa and 3.4 GPa, respectively). Theoretical values for a perfect extended-chain crystal are 300 GPa and ca. 25 GPa, and thus these early results achieved a significant fraction of the maximum modulus possible. Further developments have been on parallel fronts: melt spinning followed by solid-state drawing, and gel spinning.

Melt spinning has been adopted commercially by Celanese, SNIA, and Mitsui. Gel spinning consists of forming a dilute solution in a heavy solvent and then extruding it so that gelled PE fibers are formed on cooling and can then be drawn on conventional fiber-making equipment. The solvent has to be removed by evaporation or solvent extraction. The gel-spinning process is operated by Allied Signal and DSM. The melt-spinning process is limited to moderate molecular masses because of the polymer viscosity, but the gel-spinning process can use higher molecular mass PEs and achieves higher modulus and tensile strength (172 GPa and 3.0 GPa). Further advances may be expected on using PEs made with single-site catalysts. Since the production costs of the gel-spinning process are higher there seems to be a market for both types of product.

Limitations on the uses include the low softening temperature and creep. Creep can be reduced considerably by cross-linking [131]. For use in composites the fibers must exhibit good adhesion to epoxy resins, and this can be achieved by various methods, principally by plasma treatment [132]. PE fibers have poor compressive strength and so for composites they are usually used in combination with other reinforcing fibers such as glass or carbon. The principal market is probably in energy-absorption applications such as personal armour where the characteristics which are responsible for creep give rise to energy absorption superior to existing materials. Other applications which make use if its high modulus are in leading-edge sporting goods where it competes with carbon fiber, aramid etc. [133-132].

1.6.9. *Joining Polyethylene*

The most satisfactory method of joining PE is by welding but considerable experience is required to achieve satisfactory results. A widely used method uses a stream of hot gas (usually nitrogen to avoid oxidation) in a similar manner to gas welding of metals. The edges to be joined are chamfered to allow a bead of PE to be melted into the join. The heating causes changes in the annealed state of the PE adjacent to the join and it may become weaker than the original material, but this can be overcome by welding a reinforcing strip over the joint line [135].

Welding is used by the gas and water industries to join pipe in their distribution networks. The most satisfactory method is butt welding, in which the ends are machined true and then heated by a PTFE-insulated electrical heater. The automated machine then removes the heater and presses the ends together at a predetermined force. The procedure produces a bead of PE on the inside and outside surfaces, and the external bead is machined flush with the pipe surface.

Because of its low surface energy PE cannot be joined in its natural state by any of the strong adhesives such as epoxy resins. Rubbery adhesives such as pressure-sensitive and hot-melt adhesives function satisfactorily, but the mechanical strength of the bonding material is not very high. By treatment of the surface it is possible to form a bond with epoxies. A recommended method is oxidation with chromic acid, after which the surfaces can be glued with epoxy resin [135]. A recent development for bonding polyolefins is the use of an aliphatic amine primer that penetrates into the surface of the PE. When a cyanoacrylate adhesive is then applied, polymerization to form a bond occurs in the usual way [136].

1.7. Chemically Modified Polyethylenes

1.7.1. *Cross-Linked Polyethylene*

As noted in Section Free-Radical Catalysis, polyethylene free radicals combine to form larger molecules, unlike materials such as polypropylene, which tends to degrade. This cross-linking reaction has been made use of in a number of ways to effectively increase the molecular mass with corresponding improvements in some properties. The principal commercial methods of cross-linking [137] are:

1. Free radicals can be generated by mixing in a peroxide such as dicumyl peroxide or di-*tert*-butyl peroxide in an extruder at as low a temperature as possible and then curing the extruded cable in an external heated zone [138]. This process uses ca. 2 % peroxide and the curing process must be carried out under pressure to avoid excessive formation of voids. Peroxide together with a blowing agent is used for making foamed sheeting or molded articles, particularly of EVA.
2. Polyethylene can be cross-linked by radiation either above or below the melting point, but commercially, products are cross-linked in the solid state after the basic fabrication step. There are some differences in properties between peroxide and radiation cross-linked polyethylene due to the fact that in the solid state the cross-links occur in the existing amorphous regions, and the existing crystallinity is largely retained. Electron accelerators are used to provide the radiation in a readily controlled process [139]. Products include shrink tubing and sheeting, wire insulation, and water pipes.
3. Dow has developed a process (Sioplas-E) in which a peroxide is used to graft a vinylsilane to the polyethylene. The silane groups can then react together in the presence of moisture to form cross-links. A catalyst such as dibutyltin dilaurate is added to accelerate the cross-linking reaction. The process has the advantage that only a tenth of the amount of peroxide is required and the curing stage is simpler. However, since water must diffuse in from the surface, curing times become excessive for thick sections. The original process produced the graft polymer as a separate stage from the cable extrusion, but the Monosil process achieves the grafting in the cable extruder [140].
4. A further variant of silane cross-linking is the production of a silane copolymer by direct copolymerization of a vinylsilane in a high-pressure polyethylene reactor. This process developed by Mitsubishi for their Linklon-X polymers has been licensed to A. T. Plastics for their Aqualink process [141].

1.7.2. *Chlorinated Polyethylene*

Both LDPE and HDPE can be chlorinated to form what are in effect ethylene/vinyl chloride copolymers which are not accessible by direct polymerization. Chlorine contents of 34 – 44 wt % are reported [142]. By selection of the polyethylene and the chlorination conditions, products can be made with a range of processing viscosities and with the chlorination either randomly distributed or concentrated in segments, leaving some polyethylene crystallinity. The principal application is as a toughening agent for PVC, but there are other uses in the same general area as flexible materials such as EVA, but with the emphasis on outdoor weather resistance.

Du Pont manufacture a chlorosulfonated polyethylene (Hypalon) in which the sulfonyl groups are used in a propietary vulcanizing process. The materials are used as rubbers with good weathering properties.

1.7.3. *Fluorinated Polyethylene*

Fluorinated polyethylene is not produced as a bulk material, but surface treatment of articles with fluorine gas is used to produce a highly fluorinated surface layer. In this way the permeability of containers to a wide range of solvents can be reduced drastically. The treatment can be applied to finished articles, or fluorination can be carried out in-line by employing a dilute mixture of fluorine gas in nitrogen as the blow gas in the blow molding process [143]. Gasoline tanks are a major application, but the process is also used for containers for materials such as solvents and pesticides.

1.8. Environmental Aspects

1.8.1. *Manufacture*

Under normal operating conditions the impact on the environment of polyethylene production plants is minimal. There are some hydrocarbon emissions, particularly from those plants using solvents, but these are regulated by local legislation. In some cases hazardous materials such as the Phillips catalyst or aluminum alkyls are handled safely by attention to detail in the plant design and operation. The preparation of both peroxide initiators and Ziegler catalysts involves some extensive chemical operations with the attendant problems of waste disposal. All peroxide initiators are now made by specialist producers and there is also a tendency for this to be the case for Ziegler and Phillips catalysts.

The high-pressure autoclave process is protected against over-pressurization by bursting disks. When a disk bursts, the vessel contents, including carbonized polyethylene, are discharged quite safely to the atmosphere, but with the impression of an explosion. Thus, it is not feasible to site this type of plant as close to residential areas as would otherwise be possible.

1.8.2. *Polymer Disposal and Recycling*

At the time of writing (1997), much of the polyethylene produced is dumped into landfill within a few months of manufacture. This represents the fraction used in packaging. However, the use of disposable packaging is being increasingly called into question. In the 1970s and 1980s the concern was with the unsightliness of a material which was littering the environment, and did not degrade. Various schemes were developed to promote more rapid degradation based either on photosensitized oxidation [144] or biodegradation of blends with starch [145]. Some of these developments have reached commercialization, but now public opinion is moving towards the need to conserve plastics. Table 12 shows some of the options available to deal with the problem of disposable packaging.

Table 12. Polyethylene packaging disposal strategy

Disposal method	Advantages	Disadvantages
Incineration	avoids landfill	generates CO_2 without benefits
Incineration with energy recovery	displaces existing fossil fuel use	loss of fabrication costs
Biodegradation	removes unsightly refuse	doubts about completeness of degradation; generates CO_2 without benefits
Promoted degradation	removes unsightly refuse; lower labor costs for agricultural uses	degradation slow away from sunlight; generates CO_2 without benefits
Recycling via melt	makes use of scarce resource	some deterioration in quality
Recycling via monomer	top-quality product; processes mixed plastics	fairly large scale processing plant
Reuse	saves on fabrication costs	PE may not be the best material

Much emphasis centers on recycling, that is converting the polyethylene back into granules and then using it to produce more film etc. There is some oxidation during use and recovery, leading to some cross-linking and a slight deterioration in extrusion properties. It will be difficult therefore to match the original manufacturer's tightly controlled specification, particularly if the recovered material is of a variety of grades from different producers. There will also be a problem of suitability for use in contact with food, since the recovered material may contain a range of unknown organic and inorganic impurities. At present the intentions are to use recycled material in uncritical nonfood uses. However, a successful recycling program could outstrip such uses. Ideally recycling should be at the monomer level, but polyethylene does not readily decompose to form ethylene.

Processes have been developed which crack the plastics waste to a liquid hydrocarbon suitable for use as the feedstock to a conventional cracker, which effectively allows recycling via the monomer [146]. In the BP process plastics waste is fed to a fluidized bed reactor maintained at about 500 °C, and the liquid feedstock is recovered from the recirculating gas stream. Gaseous byproducts are used as fuel to maintain the temperature of the fluidized bed. This process has advantages over the hypothetical process of cracking PE to ethylene in that it tolerates the presence of other plastics materials, even PVC. The ever present problem of collection and transport is also eased in that the cracked feedstock could be produced in relatively small local units and transported in tankers to the refineries.

Another approach is to burn the polyethylene to recover electrical or thermal energy, thereby saving on fossil fuel which in most economies is still being used for this purpose.

2. Polypropylene

T. Geoffrey Heggs

2.1. Historical Survey

In the 1950s KARL ZIEGLER discovered new catalysts which were to revolutionize the plastics industry. Before then, propene could not be polymerized to high molecular mass products with the catalysts then available, namely, free-radical, anionic and cationic systems. Even the most favorable of these yielded only liquids consisting of many isomers and greaselike materials unsuitable for making hard plastic products.

In 1953 KARL ZIEGLER, Professor at the Max-Planck-Institut für Kohlenforschung, demonstrated that ethylene could be polymerized to a high molecular mass crystalline polymer at moderate pressure and temperature. His group had for some years been using aluminum alkyls to convert ethylene into a range of oligomers having an even number of carbon atoms. Unexpectedly, almost total conversion to butenes occurred in one experiment. The cause was eventually traced to nickel-ion contamination in the autoclave. Tests with many other metallic compounds revealed that a combination of zirconium ion with aluminum alkyl converted ethylene to high molecular mass polymer. Further searching revealed that titanium ion was even more active in producing polyethylene (November 1953). Such combinations of transition metal compounds with an aluminum alkyl later became known as Ziegler – Natta Catalysts, thereby acknowledging the immense contribution of GIULIO NATTA to discovering and characterizing polypropylene (PP) and other α-olefin polymers in 1954.

NATTA, Professor and Director of the Milan Institute of Industrial Chemistry, was a consultant to Montecatini, to whom NATTA assigned his patents. The close collaboration between ZIEGLER and NATTA was acknowledged in 1963 by the joint award of a Nobel prize in Chemistry for their outstanding contributions to polymer science. A fascinating account of ZIEGLER and NATTA's personal approach to these discoveries is provided by MCMILLAN [147].

In the the United States, patents on crystalline polypropylene were awarded originally to NATTA et al. (on behalf of Montecatini), but were overturned later in favor of Phillips Petroleum Company. The immense legal procedings to establish inventor rights to crystalline polypropylene in the United States are outlined by HOGAN and BANKS [148], with more recent comments by PINO and MORETTI on this costly litigation [149]. Phillip's polymerization catalyst, consisting of chromium-ion promoted silica – alumina, has not been used in any commercial plant to manufacture crystalline polypropylene.

Notwithstanding the complexities and hazardous nature of these new coordinated catalysts, industrialists and academe alike were stimulated by ZIEGLER and NATTA's prompt and prolific disclosures concerning this new, high-melting polymer. Industrial-scale production of PP started at Ferrara, Italy, in 1957 with a 6×10^3 t/a plant. By the end of 1994 global capacity had risen to 20.5×10^3 t/a (Table 13), spread over 35 countries [150]; today, new plants are expected to be capable of producing 200×10^3 t/a to achieve reasonable economies of scale.

Table 13. Global PP capacity (10^3 t/a) and its distribution

Country/region	End 1990	End 1994	Growth * 1990 – 1994, %
Western Europe	4530	5705	26
North America	4400	5440	24
Japan	1870	2656	42
Other Far East/Australia	2734	4090	50
Middle East/Africa	280	655	34
South America	450	1035	30
Eastern Europe	790	930	18
Total/average	15 054	20 511	36

* 7 % per annum growth for four years is 31 % total growth.

There are several reasons for this phenomenal growth, which exceeds that of other bulk plastics [151] (Table 14). At first propene was readily available, almost at byproduct prices, from petrochemical cracker plants making ethylene. The polymer itself was suitable for a wide range of existing and new applications such as films, various fibers, large and small moldings from boat hulls to instrument parts. In addition, new manufacturing technologies based on $MgCl_2$ supported catalyst systems yielded both cost savings and improved products by eliminating atactic PP removal steps and then the deashing stage. Some 40 years on there are expectations that the new metallocene catalyts will extend these uses, even to the extent of challenging products such as polyamide, ABS, and flexible PVC for part of their market [152].

Table 14. Major polymer usage in Western Europe

Polymer	Consumption, 10^3 t/a			Growth rate, %	
	1974	1984	1994	'74/'84	'84/'94
LLDPE +LDPE	3080	4089	6015	33	47

PP	680	1895	5178	179	173

2.2. Polymer Structure

2.2.1. *Molecular and Chain Structure*

Polypropylene is a synthetic, high molecular mass linear addition polymer of propene. In 1954/5, NATTA et al. prepared sufficiently large amounts of PP to isolate and characterize various stereoisomers. This led to a new descriptive nomenclature still used today. Commercial interest lies primarily in highly crystalline PP, together with its further modifications through copolymerization.

In perfectly isotactic PP, each monomer unit in the chain is arranged in a regular head-to-tail assembly without any branching or 1,3 additions (Fig. 21 A). This is the result of template-type constraints by the heterogeneous stereospecific catalyst. In practice such perfection is hard to achieve. An occasional error (Fig. 21 B), averaging about 0.3 – 1.5 per hundred chain links, occurs in some, but not equally in all chains. The multisite nature of solid catalysts is thought to be responsible for this behavior.

Figure 21. PP chain structures

Solvay and $MgCl_2$ supported systems reduce the extent of these errors, and with them the amount of noncrystalline (atactic) polymer. Still at the development stage, metallocene-based single-site catalysts (SSCs) also produce stereoregularity errors, but these seem to be distributed more uniformly along the chains, regardless of their length (Fig. 21 E). This contrasts with multisite catalysts (MSCs), for which misplacements vary in frequency and in number. The tendency here is for the high molecular mass fraction to contain fewer faults, while the short chains suffer from excessive dispruptions, which lead to reduced crystallinity.

Until recently, syndiotactic PP (Fig. 21 C) was not commercially important because of unacceptable polymerization difficulties at low temperatures. Some metallocene catalysts overcome this problem to produce a regular sequence of racemic (r) propene placements yielding a crystalline polymer melting at 130 °C. Mitsui Toatsu and Fina have entered into a joint venture to assess costs and customer reaction to syndiotactic PP.

Complete loss of steric regulation generates atactic polymer chains (Fig. 21 D), incapable of crystallizing. Hitherto this low molecular mass byproduct had only a few commercial outlets for adhesives. The position could change with the emergence of high molecular mass versions deliberately made with a metallocene-based catalyst, $[(Me_2SiFlu_2)ZrCl_2]$ (Flu = fluorenyl)[153].

All Ziegler – Natta commercial polymers have broad molecular mass distributions within the range M_w/M_n = 5 – 10 for ex-reactor material. Any reduction is achieved by

peroxide-induced chain clipping in an extruder. Metallocene polymers have narrower distributions (M_w/M_n = 2 – 4) as a consequence of their single-site mechanism. This avoids the need for peroxide additives, which produce objectionable odor and volatile byproducts.

2.2.2. *Crystallization and Morphology*

Polypropylene's strength and versatility stem from a matrix of interlocking crystallites that allow formation of rigid and tough articles. Highly isotactic polymer, with its regular structure, forms a helical coil having three monomer units per turn. These coils stack together into thin lamellar crystallites which force the chains to fold several times as they emerge and reenter lamellae. Polyethylene behaves similarly (see Fig. 2)

While the equilibrium (i.e., thermodynamic) melting point is 188 °C, at normal analysis heating rates the final melting point is ca. 160 – 170 °C. Three crystalline forms are known (Table 15), of which the α-form is the most stable. Rapid quenching yields the β-form with a lower density and melting point of 150 °C. Polymers of lower stereoregularity and random copolymers usually contain γ- crystallites in addition to the α-form.

Table 15. Crystal habits of PP [154-156]

Crystal form	System	Crystal density (20 °C), g/cm^3	Chains per unit cell	*mp*, °C *
Iso α	monoclinic	0.932 – 0.943	4	171
Iso β	pseudo hexagonal	0.922	9	150
Iso γ	triclinic	0.939	1	131
Smectic		0.916		
Amorphous		0.85		
Syndio	orthorhombic	0.93	2 (4/1 helix)	138

* The enthalpy of melting for 100 % crystalline isotactic PP is variously reported, due to different techniques. WUNDERLICH [154] gives 165 ± 18 J/g, BRANDRUP and IMMERGUT report 209 J/g [155], the ICI DSC standard is 185 J/g, and the Shell DSC standard is 188emsp14;J/g [157, p. 590].

Crystallization is complicated further by assembly of these lamellar crystals into larger structures, called spherulites. These have radial symmetry and can adopt five different forms (Table 16). While the size of the crystallites is in the region of 10 – 50 nm, too small to scatter visible light (400 – 600 nm), spherulites are much larger (10^3 – 10^5 nm). The latter are responsible for the translucency of slowly cooled PP moldings. Rapid crystallization from the melt by fast cooling, adding nucleating agents, and reducing spherulite sizes by stretching a partially solidified melt all improve transparency.

Table 16. Spherulitic structures

Spherulite type	Crystal type	Features
I	α	positive birefringence, lost at 160 – 170°C; epitaxial branching; always associated with type II
II	α	negative birefringence, lost at 160 – 170 °C; fibrillar crystals radiating from nucleus; most stable of all spherulites
III	β	strongly negative birefringence; associated with β-crystals and high shear in cooling; melts and reverts to type II at 145 –150 °C
IV	β	special case of Type III, characterized by banded concentric rings
V	γ	rare variant formed under high pressure with γ-crystals

Crystallization from a viscous melt is hindered by chain entanglements and by the need for helices to fold as they close-pack into lamellae. This, and the formation of nuclei might contribute to the low degree of crystallization even in highly stereoregular polymers. Typically, the onset of crystallization occurs at ca. 110 – 120 °C in DSC instruments. This point coincides with the cooling peak for polyethylene, whose presence would be masked in blends and in ethylene copolymers. Using the melting curve overcomes this analytical difficulty. Another aspect of tardy crystallization is the low level of crystallinity in fabricated items, even when highly stereoregular polymers are used. Commercial articles vary from 30 % crystallinity in rapidly quenched films to 50 – 60 % in moldings. Even purified and annealed samples of highly stereoregular PP rarely achieve more than 70 % crystallinity. Polypropylene is properly regarded as a semicrystalline polymer for these reasons.

2.3. Raw Materials

2.3.1. *Propene*

Sensitive Ziegler – Natta catalysts require pure propene to ensure high polymerization rates and good yields of isotactic polymer, without wasteful byproducts. Harmful impurities can be grouped into two main categories which have different effects on the process. The most destructive contaminants are polar and highly unsaturated compounds which react directly with the catalyst systems, retarding polymerization and impairing stereospecificity. Examples include acetylenes, dienes, carbon monoxide and dioxide, carbonyl sulfide, water, alcohols, and ammonia. The second group contains materials which adversely influence the process, but not the chemistry, by raising the pressure during reaction due to an accumulation of inert substances. These further complicate the monomer recovery section and recycle streams. This group contains materials such as methane, ethane, propane, butane, and nitrogen.

Most manufacturers use polymer-grade propene as feedstock, which can be further refined by passing it through local guard columns containing alkali, molecular sieve, alumina, supported copper, etc. to guarantee consistently high purity [158], [159]. Typically, monomer conforming to the following specification, is adequate for most plants, but certain sensitive supported catalysts require the lower levels listed for carbonyl sulfide, carbon monoxide, and oxygen (this quality is said to be suitable for metallocene catalysts) [160]:

Propene	99.5	wt % min.
Propadiene	5	vol ppm max.
Propyne	5	vol ppm max.
Butadienes	10	vol ppm max.
Oxygen	5 – 2	vol ppm max.
Carbon monoxide	3 – 0.3	vol ppm max.
Carbon dioxide	5	vol ppm max.
Carbonyl sulfide	0.5 – 0.03	vol ppm max.
Total sulfur	1	wt ppm max.
Water	5	wt ppm max.
Methanol	5	vol ppm max.
Ammonia	1	vol ppm max.
Ethane	500	vol ppm
Propane	0.5	wt %
Butane	500	vol ppm
$N_2 + CH_4$	300	vol ppm
Isobutene	50	vol ppm (estimated)
Hydrogen	10	vol ppm max.
Ethylene	50	vol ppm max.

1-Butene	50 vol ppm max.

Ethylene and 1-butene copolymerize with propene to marginally reduce the polymer softening point. Hydrogen is a powerful chain-transfer agent whose concentration must be accurately controlled in the reactor.

Propene is normally manufactured outside the PP plant. An important source of both ethylene and propene, in the approximate weight ratio of 2: 1, is from steam cracking naphtha or gas oil at 700 – 950 °C, followed by fractionation. Refinery catalytic cracking of petroleum products yields 2 – 5 % of propene, which is isolated as a chemical grade containing 90 – 95 % of the monomer with much propane. This can be purified further to polymer-grade specification, but some PP plants which are able to handle the extra propane may bypass further refining or add a simplified hydrogenation unit to reduce dienes [161]. These possibilities arise at the milder end of the cracking range of 400 – 500 °C, which then generates lower amounts of harmful highly unsaturated products. Currently there is some interest in building propane dehydrogenation plants as a third source of pure propene [161], [162].

Some properties of propene relevant to polypropylene production are as follows:

Heat of polymerization	2514 kJ/kg
bp	– 47.7 °C
Critical temperature	92 °C
Critical pressure	4.6 MPa
Vapor pressure at 20 °C	0.98 MPa

2.3.2. *Polymerization Diluents*

Most early processes and some current plants use an inert hydrocarbon diluent in the reactor to help transfer propene to the solid catalyst and to convey reaction heat to the water- cooled jacket. Typically there is twice as much diluent in the reactor as polymer; thus, the purity demands on the diluent are as important as for the monomer. Refined petroleum fractions and synthetic hydrocarbons in the C_6 – C_8 range perform well, while solvents ranging from butane to dodecane are also used commercially.

Polar impurities, such as alcohols, carbonyl compounds, water, and sulfur- containing compounds must be kept below 1 – 5 ppm. The content of aromatics should be below 0.1 – 0.5 vol %, depending on the catalyst employed. Here UV spectroscopy, supplemented with IR spectroscopy and refractive index measurement, is used to monitor quality. Regular checks must be made on recycled-diluent quality to prevent oxidized species and catalyst fragments accumulating unnoticed.

Polypropylene articles, such as films and containers, are widely used for food packaging and handling. In these cases the diluents and other additives must conform with the appropriate health regulations.

Since polymerizations carried out in the gas phase or in liquid propene only use small amounts of diluent as catalyst carriers, their purity requirements are less stringent.

2.3.3. *Catalyst Preparation [163]*

All current commercial manufacturing processes for highly isotactic PP use heterogeneous Ziegler – Natta catalyst systems. These two-component initiators consist of a solid transition-metal halide, usually $TiCl_3$, and an organoaluminum alkylating agent such as diethylaluminum chloride (DEAC). This system was the basis of PP plants until about 1980 when supported catalysts were commercialized. An overview of the four development phases is given in Table 17.

Table 17. Catalyst development

System	Catalyst performance		Plant
	Activity, kg PP/g catalyst	I.I. *, wt %	process
1st Generation			
1957 – 1970	0.8 – 1.2	88 – 93	deash and remove
$TiCl_3 \cdot AlEt_2Cl$			atactic
2nd Generation			
1970 – 1980	3 – 5	92 – 97	deash/deactivate,
$TiCl_3 \cdot AlEt_2Cl$ +			atactic usually remains
Lewis base (Solvay)			
3rd Generation			
1980 – 1990	5 – 20	≥ 98	no deash and
$MgCl_2$-supported $TiCl_4 \cdot AlEt_3$			no atactic removal
4th Generation			
1995	ca. 20	?	no deash and
Metallocene/MAO systems			no atactic removal
			MMD ca. 2 – 4

* Isotactic index (% insoluble in boiling heptane).

2.3.3.1. *$TiCl_3$-Based Catalysts*

Of the four known crystalline forms of $TiCl_3$, three are purple (α, γ, δ) while the fourth is brown (β). The latter is not used in PP manufacture because of its poor stereospecificity. All the purple forms have a layer lattice consisting of closely packed chlorine atoms (Fig. 22) either hexagonal (α), cubic (γ), or intermediate between the two (δ). Preparative methods are critical to achieve good stereoregulation and high activity with these catalyst components.

Figure 22. Layer lattice of α-$TiCl_3$ [165] (printed with permission of Harwood Academic Publishers)

Early work by the NATTA school used pure $TiCl_3$ made by hydrogen reduction of $TiCl_4$, followed by ball milling to give a high surface area.

$$TiCl_4 + 1/2\,H_2 \rightarrow TiCl_3 + HCl$$

A more active form is made by reduction with aluminum powder, followed by ball milling.

$$3\,TiCl_4 + Al \rightarrow 3\,TiCl_3 \cdot AlCl_3$$

Much of the aluminum chloride is present as a true solid solution in crystalline δ-$TiCl_3$. This catalyst has a larger surface area of 10 – 40 m^2/g and is commercially available

from several companies. Nowadays, a Lewis base, such as an ester or ketone, may be introduced at the milling stage to increase stereospecificity.

Another important route dispenses with ball milling by reducing a hydrocarbon solution of $TiCl_4$ with an organoaluminum compound below room temperature. Di- and trialkylaluminum compounds are suitable. In this process the titanium trichloride precipitates in the brown, β form. Heating to 80 – 120 °C completes the reduction and transforms this solid to the required purple variety. Several hydrocarbon washes remove some of the aluminum compounds to leave an active, stereospecific catalyst. A useful aspect of this technique is that conditions can be selected to precipitate spherical catalyst particles. Subsequent propene polymerization then yields spherical polymer particles that exhibit good flow characteristics. This ability to replicate the shape of catalyst particles is quite general in Ziegler – Natta polymerization. Polymer forms throughout the agglomerate of small catalyst clusters, expanding the particle uniformly in all dimensions as polymerization continues.

Major refinements in alkyl-reduced $TiCl_3$ systems were made by Solvay [164-166] in their three-stage process, which gives a 4 – 5-fold increase in activity:

1. Titanium tetrachloride solution is reduced with diethylaluminum chloride at 0 °C
   $TiCl_4 + AlEt_2Cl \longrightarrow TiCl_3 \cdot x\,AlCl_3 \cdot z\,AlEtCl_2$
   where $x = 0.15$, $z = 0.20$
2. The brown β-$TiCl_3$ solid is treated with diisoamyl ether to dissolve out most of the aluminum compounds
3. The extracted solid is reacted with neat titanium tetrachloride at 65 °C to transform the β crystallites to the violet δ-form

The novelty lies in removing much of the aluminum residues at the β stage, without collapsing the particle, and then transforming to the stereoregulating δ-form while retaining a spongelike structure with a surface area of 150 m^2/g [164]. Analogous commercial products are available in Japan and the United States.

2.3.3.2. *Supported Catalysts*

The third-generation, supported titanium catalysts, are based on research by Montedison (now Montell) in Italy and Mitsui Petrochemical Industries (now Mitsui Sekka) in Japan. Collaboration and cross-licensing between these two companies avoided incipient interference claims. Starting around 1968 with finely milled magnesium chloride, which has a similar layer structure to violet $TiCl_3$, ways were discovered of depositing stereoregulating titanium compounds on the surface.

A particle-form supported catalyst may be prepared as follows [167]:

1. A spheroidal support is prepared by making a fine dispersion of molten (125 °C) magnesium chloride ethanolate complex in hot kerosene containing sorbitan distearate as surfactant. The dispersion is quenched by pumping into kerosene at – 15 °C to give particles with a diameter of 5 – 30 µm.
2. A slurry of the particles is added to neat $TiCl_4$ at 20 °C.
3. Diisobutyl phthalate (17 % v/w) is added and the mixture heated to 120 °C.
4. Decant, and heat with further $TiCl_4$ to 130 °C. Isolate by hot filtration and washing. The product contains 2.3 wt % Ti, 63 wt % Cl, 20 wt % Mg, and 9.9 wt % diisobutyl phthalate.

For the polymerization of propene, triethylaluminum is used as a cocatalyst, and phenyltriethoxysilane as an additional external Lewis base stereoregulator. Potential corrosion problems have been substantially reduced by using the chlorine-free triethylaluminum.

By ca.1980, commercial plants were achieving 20 – 30 kg polymer per gram catalyst, and the isotactic index progressively improved from 88 to 99 %.

These catalysts form the basis of advanced technology plants in which deashing (removal of catalyst residues) and atactic polymer separation can be eliminated entirely [168]. It is estimated that by 1998 70 % of global plants will be operated with such “high mileage” technology. Coupled with this is the possibility of exploiting the good handling characteristics of the Spheripol coarse particle-form powders, thus dispensing with the need for expensive pelletizing plant. The segregation of added powdered stabilizers during storage and the problems of handling such mixtures are addressed, to some degree, by Montell's Valtec products, in which the additives are treated to provide a hard coating on the polymer. Some customers still prefer to handle traditional granules from an extruder.

2.3.3.3. *Homogeneous Catalysts [163],[169], [170],*

Metallocenes have been used for 30 years as model compounds for Ziegler – Natta reactions. They were quite unsuitable for commercial reactors because of their extremely low activity and poor stereocontrol. In the early 1980s, Sinn and Kaminsky serendipitously discovered that replacing triethylaluminum with methyaluminoxane (MAO) enormously increased the polymerization rate of ethylene when combined with a substituted zirconocene dichloride. There were several other major hurdles to overcome before a suitable candidate was available for use in PP plant. Low stereospecificity succumbed to a more stereorigid metallocene, and the poor reactivity and polymerization temperature restrictions were solved by further molecular tailoring. Trials were conducted in 1996 on commercial-scale streams.

Metallocences suitable for isotactic PP manufacture generally seem to be based on zirconocenes supported on inert solids to preserve particle size and shape. This makes them more compatible with the advanced process technologies of the major operators who refer to them as “drop-in catalysts”. Sophisticated chemistry (Figure 23) is needed to prepare the base metallocenes, many of which have been made only in laboratory-scale equipment. An additional constraint is the heavy patenting, already amounting to some 900 applications since 1984. Hoechst, Exxon, Fina, Mitsui, and BASF together hold half of these.

Figure 23. Hoechst (left) and BASF metallocenes

The great versatility of single-site metallocenes has been demonstrated in trials that yielded improved and novel polymers. It remains to be seen how many of these desirable features can be incorporated in a single catalyst and how easily appropriate changes can be introduced at plant level. Some of these polymer properties are mentioned in Section Homopolymer [169].

2.3.3.4. *Aluminum Alkyl Cocatalysts.*

Nowadays, aluminum alkyls are purchased from outside manufacturers. In the case of DEAC systems it is necessary to tailor the chlorine content to the type of $TiCl_3$ used. As the various alkyls interact rapidly, it is simple to adjust the composition by adding $AlEt_3$ or $AlEtCl_2$:

$$2\,AlEt_2Cl \rightleftharpoons AlEtCl_2 + AlEt_3$$

Triethylaluminum is made commercially from aluminum, ethylene, and hydrogen. Care should be taken to avoid the high levels of the hydride that are sometimes present. Trimethylaluminum is available from outside maufacturers, as is methyl aluminoxane (MAO). The latter is made by the controlled addition of water to the trialkyl with various techniques to moderate the potentially violent reaction. One method uses a salt hydrate, such as such as hydrated potassium aluminum sulfate (potassium alum). Various grades of MAO are available, possibly due to the different manufacturing methods and the polymeric nature of the product, which contains linear and cyclic short chains.

2.3.4. ***Hydrogen***

Pure hydrogen is used at concentrations of 0.05 – 1 vol % based on propene to control molecular mass. Polar and highly unsaturated contaminants should be excluded, as usual.

where ⌇⌇⌇ = polymer chain.

2.4. Polymerization Mechanism

Many kinetic and theoretical models have been applied to Ziegler catalysts. Only a very small proportion (< 1 %) of the titanium atoms in violet $TiCl_3$ are active for stereospecific polymerization. Cossee proposed that an active site is generated at those surface titanium atoms which have one chloride vacancy and one exposed and weakly bound chloride anion, the remaining four chlorine atoms being firmly held in the lattice. These sites are located on the lateral faces of violet $TiCl_3$ crystals where the protruding chlorine is alkylated by aluminum alkyl (Fig. 24 A). An incoming propene molecule approaches this active site (Fig. 24. B), whose immediate crystal geometry controls both the initial coordination and the configuration as the monomer inserts into the titanium – alkyl σ-bond (Fig. 24 C). Accordingly, this is a template type [171] polymerization controlled by the surface shape, and not by the previously inserted monomer unit. Atactic polymer is formed at more open surface sites having two vacancies

or two weakly bonded chlorine atoms. While there are a number of alternative proposals [163], [172], [173] the essentials of the Cossee – Arlman model are widely accepted.

Figure 24. Cossee – Arlman model for polymerization site

A) Alkylation of lateral surface chlorine; B) Propene complex; C) Insertion into Ti – C_2H_5 σ-bond

Since each active site on the crystal is unlikely to be unique, a distribution of imperfections is to be expected. Sometimes Ziegler – Natta catalysts are referred to now as multisite catalysts to emphasize this wide distribution of polymer chain lengths and stereoregularities.

In $MgCl_2$ supported titanium chloride systems, 10 – 20 % of the titanium is thought to be in the form of active sites, substantially more than in Solvay's improved catalyst, which contains ca. 0.8 – 2.7 % of the titanium in active form. Surface geometry still controls stereoregularity, but Lewis bases are much involved in this regulation [174].

The new (1996) metallocene single-site catalysts have unique structures which secure precise control and definition of the active site. Consequently, a narrow molecular mass distribution and better control of chain irregularities, now including new types of chain defects, may be obtained with selected metallocenes/aluminoxanes. These catalysts can be used in solution, but manufacturers usually prefer them supported to secure better control of particle size and shape, together with freedom from reactor build-up [170]. Apparently certain supports can be used without spoiling catalyst or plant performance. Hence the name drop-in catalysts to emphasize the ease with which they can be introduced into existing plant. Their considerable potential and performance are being tested at the pilot-plant stage [175].

2.5. Industrial Processes

In the laboratory, it is a fairly simple matter to make a sample of PP from a given catalyst. All that is necessary is to suspend the solid transition metal compound in dry, inert-gas-blanketed, pure heptane containing aluminum alkyl cocatalyst and then bubble in propene gas at about 60 °C and atmospheric pressure. Polymer forms as a white solid permeating the catalyst particles which give an overall red-pink hue (with $TiCl_3$). Elevated pressures increase reaction rates according to a first order law.

Industrial manufacturing plants must incorporate many other stages to secure salable product: some of these complications are eliminated in modern high-technology plants by using advanced catalysts. Here the residual catalyst and atactic levels can be sufficiently low not to discolor polymer nor to generate odor and smoking. Although older plants still using the traditional process make high quality products, their higher cost base means that they are becoming increasingly uncompetitive, except in some highly specialized and low-tonnage applications. Some 70 % of global PP plants have installed new "High Mileage" processes.

The following sections describe one older slurry type of plant and four state-of-the-art advanced processes. From these it will be possible to visualize a number of hybrid alternatives to suit particular catalyst characteristics [178]. Copolymerization is dealt with separately for each system in Section Copolymerization, though for convenience the process flow sheets illustrating homopolymerization (Figs. 26, 27 and 29) include the bolt-on copolymer plant.

2.5.1. *Suspension Homopolymerization (Early Diluent Processes)*

Details of the individual steps shown in Figure 25 vary between manufacturers as regards process conditions and type of equipment.

Figure 25. Schematic of early PP manufacturing process

Polymerization. For continuous systems, which have largely superseded batch polymerization, the mean residence time of catalyst in the reactor(s) is usually 1.3 – 3 h. Individual autoclaves started out as 10 – 30 m^3 vessels, but as stream capacities increased sizes up to 100 m^3 have been installed. Another common practice involves linking reactors together in series or in parallel configurations. The maximum output rate of a reactor is determined by the heat removal system, which no longer relies simply on water- cooled polymerizer jackets. Internal and external cooling circuits provide the necessary extra cooling at these high rates (> 0.3 t h^{-1} m^{-3}).

It is only necessary to meter catalyst into the first reactor of a cascade system, both because the activity decay is fairly small, and because it is not desirable on quality grounds to generate a second family of particles downstream. Propylene and hydrogen feeds to each reactor maintain the required pressure and gas compositions to secure the correct polymerization rate and molecular mass. Most of the reaction diluent is metered into the first vessel in the train, but some can be added further downstream to minimize fouling as the polymer concentration increases. Slurry viscosity increases rapidly during the latter stages of polymerization as the swollen polymer particles approach close packing. This point is strongly dependent on the size and shape of the catalyst particles. Seldom will the slurry concentration be allowed to exceed 42 wt % unless a very low density diluent is used.

As a rule, polymerization temperatures lie between 50 and 75 °C; the desirability of using a higher temperature being countered by decreased catalyst stereospecificity causing increased solubles and poorer properties. While reactor pressures of 0.5 – 1.0 MPa typified earlier plants, intensified processes expand this to 2 MPa.

Propene Flashing and Recovery. Two ways of removing and recovering unreacted propene, stages b and k in Figure 25, are practiced commercially. Most commonly, slurry from the last reactor discharges into a heated vessel at lower pressure to flash off propene vapor and other volatiles. After cooling and condensation, fractional distillation recovers pure propene as an overhead stream with a bottom discharge of propane and some diluent. In certain cases it is more economical to return the flashed propene to an adjacent plant for use there. The alternative scheme simply allows polymerization to continue without feeding any fresh propene to the latter part of the reaction train. Propene in solution is gradually converted into polymer as the polymerization rate falls exponentionally in the first-order reaction. This simple scheme entirely eliminates the recovery stage, but it does call for additional reactors working at low rates.

Catalyst Removal (Deashing). Catalyst removal, steps c and d in Figure 25, involves the extraction of highly polar particulate $TiCl_3$ from a hydrophobic polymer particle. Procedures differ appreciably, but the first step always converts titanium and aluminum residues into complexes or alkoxides that are soluble in the diluent, usually by heating to 60 °C with 2 – 20 % of an alcohol, though acetylacetone has also been used. The choice of ethanol, propanol, or butanol is influenced by the diluent boiling point and subsequent recovery schemes.

Step d, Figure 25, shows a widely practised arrangement whereby water washing is used to transfer all these catalyst complexes into an aqueous phase, leaving behind a purified polymer slurry.

$$\underset{\text{(in hydrocarbon)}}{TiCl_3 \cdot (ROH)_4} + H_2O \longrightarrow \underset{\text{(in aqueous soln.)}}{Ti^{3+} + 3\,Cl^-}$$

It is vital to work with either a strongly acidic or strongly alkaline complexing medium to repress hydrolysis and polycondensation, which impair the extraction efficiency. This technique normally yields polymer containing 10 – 30 ppm of Ti, 10 – 40 ppm of Al, and 20 – 40 ppm of Cl residues. Very pure polymer can be made in an alternative form of step d. Here, the polymer is isolated by filtration, and is repeatedly washed by reslurrying in diluent/alcohol mixtures to remove all solubilized catalyst without introducing water. This process adds to the load on diluent and alcohol recovery, but PP quality improves.

Centrifuging. Centrifuging the deashed slurry (step e, Figure 25) removes most of the free diluent, but the wet cake can still hold up to 50 wt % (dry basis) of diluent containing dissolved atactic polymer. Depending on the grade of polymer being produced, it is sometimes beneficial to introduce a washing stage with diluent while centrifuging to reduce the amount of soluble polymer in the final product. Centrifuges can be of the filtering (basket) or decanting type according to the powder characteristics.

Drying. Drying the wet cake sometimes requires more than one stage, particularly in processes using high-boiling solvents. Steam distillation removes most of the diluent to leave an aqueous slurry from which the polymer is readily isolated by filtration. A conventional drier removes the small amount of water still adhering to the hydrophobic

particles. More elaborate driers, operating under a nitrogen atmosphere, remove diluent directly in flash drying, fluidized beds, or hot surface contact type systems. Before the advent of high-technology systems (Section Spheripol Process), some manufacturers had already improved catalyst stereospecifity such that the low level of atactic polymer in the diluent could be left in the product. In this case, the total slurry can be dried without previous centrifugation. This avoids all atactic polymer handling problems. All these drying stages must use nitrogen blankets throughout to minimize hazards with flammable hydrocarbons, as well as to protect the polymer.

Extrusion and Pelletizing. Powder leaving the driers at about 100 – 120 °C can be fed directly to a pelletizing extruder, in which it is stabilized and converted into dense granules. As intermediate powder storage is often necessary, common practice introduces a cooling stage to 70 – 80 °C to prevent adventitious oxidation when antioxidants are absent.

Diluent and Alcohol Recovery. An essential part of the schematic plant shown in Figure 25 is solvent and alcohol recovery, and atactic polymer separation (stages h – j). Diluent from the centrifuge contains soluble polymer and traces of alcohol. This mixture, together with liquid from the driers, is separated by multistage distillation. Pure diluent is then recycled to the polymerizers, while viscous atactic polymer separates out as a heavy end. Wiped film evaporators can be used to strip the last traces of diluent from highly viscous solutions.

Most of the alcohol is recovered from the first few water washes by fractional distillation (step h) followed by azeotrope splitting.

2.5.2. *Bulk Polymerization in Liquid Propene*

A special case of the slurry is to use liquid propene, with its poorer solvent power, instead of an inert diluent. Polymerization rates increase considerably with pressures around 3 – 4 MPa. Stirred autoclaves incorporating evaporative cooling, and loop reactors provide good heat-transfer rates. The chemistry parallels that described in Section Suspension Homopolymerization (Early Diluent Processes), but the engineering demands are greater [178]. After polymerization, the catalyst is solubilized with polar complexing agents to permit extraction from the polymer by countercurrent washing with liquid propene. Hybrid plants are known which use liquid propene for polymerization, followed by flashing and resuspension in heptane for polymer deashing.

2.5.3. *Solution Polymerization*

In contradistinction to polyethylene manufacture, solution polymerization at high temperature is rarely practiced for isotactic PP. Special catalysts are necessary to minimize the customary reduction in stereospecificity above 100 °C, but the activity and stereoregularity still remains too low to dispense with catalyst extraction and removal of atactic PP. The original Eastman – Kodak process makes grades for some special markets, but there are no plans for further new plants along these lines. While polymerization at ca. 150 – 200 °C should permit some useful recovery of polymerization heat, overall costs are high for isotactic PP. It is reported [179] that the solution process is being used to make atactic PP, for which it seems more suited. Commercial plants dedicated to make only atactic PP have been announced by Himont (Canada), El Paso (Texas), and Huls (Germany).

2.5.4. *Spheripol Process [180]*

Figure 26 depicts a modern state-of-the-art plant based on Himont technology [180] for making homopolymer and impact copolymers (Section Impact (Block) Copolymerization) with supported catalysts. The latter are sufficiently active not to require any catalyst extraction, nor removal of atactic polymer because of the high stereospecificity. Homopolymerization takes place at ca. 70 °C and 4 MPa in liquid propene circulating round one or more loop reactors. A single axial flow agitator in each loop maintains high flow rates to ensure good heat transfer to the water-cooled jackets, whilst also preventing any polymer particles settling from the slurry [181]. Typically the PP concentration is ca. 40 wt %.

Figure 26. Spheripol process

a) Loop reactors; b) Primary cyclone; c) Copolymer fluidized bed; d) Secondary and copolymer cyclone; e) Deactivation; f) Purging

Continuously metered catalyst, triethylaluminum, and a Lewis base stereoregulator such as a dialkyldimethoxysilane are fed into the reactor to maintain polymerization and stereocontrol. The initial few seconds of polymerization with a new high-activity catalyst particle are quite critical to secure good performance. For this reason, some processes have a prepolymerization stage in which the catalyst components react at lower temperature and monomer concentration. This can be either a batch or continuous pretreatment which produces only small amounts of polymer (< 100 g/g) in the catalyst. This prepolymerized catalyst is then fed into the loop reactor as usual. Mean residence time in a single polymerizer is 1 – 2 h. Two loop reactors can be operated in series to narrow residence time distributions, modify the polymer, and increase output.

A continuous stream of polymer slurry discharges through a heated zone for the first stage of pressure let down in cyclone (b). For homopolymers, this connects directly to the secondary cyclone (d), bypassing the copolymerization unit (Section Impact (Block) Copolymerization). Unreacted propene flashes off from the first cyclone and is condensed with cooling water and recycled to the reactor. A compressor is required for gas from cyclone (d). Polymer powder from the cyclone is fed into vessel (e) for deactivation with small amounts of steam and undisclosed additives. Residual moisture and volatiles are removed by a hot nitrogen purge in vessel (f) before conveying polymer to storage silos for conventional finishing as stabilized powder or extruded pellets.

Provided the expensive extrusion stage can be dispensed with by selling powder, then it is claimed that the capital cost of Himonts Spheripol process is only 50 % of the suspension process described in Section Suspension Homopolymerization (Early Diluent Processes) [180].

2.5.5. *Hypol Process*

Mitsui Petrochemical, co-inventor with Himont of the supported catalyst system, has developed an analogous cheap process using bulk polymerization with their own supported catalysts. It differs from the Spheripol system in that batch prepolymerization is used with washing. Two conventional stirred polymerizers are used in series, with heat removal by evaporative cooling of liquid propene in the reactors. Slurry is then discharged into a stirred, heated flash vessel, where propene is recovered from polymer, as in the Himont system.

2.5.6. *Gas-Phase Processes*

In gas-phase processes, gaseous propene is contacted with solid catalyst intimately dispersed in dry polymer powder. Industry uses two different methods of carrying out this reaction depending on the chosen method of heat removal. The Union Carbide/Shell process uses an adaptation of the Unipol polyethylene fluidized-bed system. BASF and Amoco use mechanically agitated dry powder beds with evaporative cooling in vertical and horizontal autoclaves, respectively.

BASF Novolen Process [182]. Figure 27 shows the BASF continuous process for making homopolymers, impact copolymers, and random propylene – ethylene copolymers using high-activity, highly stereospecific catalysts. The reactor vessels, of 25, 50, or 75 m^3 capacity, are equipped with proprietary helical agitators, which give excellent agitation. Homopolymerization needs only the primary reactor, into which the catalyst components are fed. These must be very well dispersed in the powder bed to avoid build-up. The reaction conditions of 70 – 80 °C and 3 – 4 MPa ensure that the monomer phase is gaseous in the reactor. Low concentrations of hydrogen are used to control molecular mass over wide ranges. The temperature is controlled by removing gaseous propene from the reactor head space, condensing it with cooling water, and then recirculating it back into the reactor, where its evaporation provides the required cooling, as well as further aeration of the stirred powder bed. Each tonne of polymer made requires ca. 6 t of liquid propene to be evaporated as coolant.

Figure 27. BASF gas-phase Novolen process

a) Primary reactor; b) Copolymerizer; c) Compressors; d) Condensers; e) Liquid pump; f) Filters; g) Primary cyclone; h) Deactivation/purge

Powder and associated gas discharge continuously from the primary reactor dip tube directly into a low-pressure cyclone (g). Propene carrier gas from this cyclone is recycled to the reactor after compression, liquifaction, and, sometimes, distillation. The powder then passes to a purge vessel where a deactivator quenches all residual catalyst activity, and nitrogen strips out traces of propene from the hot powder. From here powder is conveyed into silos for stabilization and extrusion into granules. BASF also offers a post-granulation steam-stripping package to remove any oligomers and oxidized residues from the granules for demanding applications.

BASF pioneered their gas-phase process with commercial production in 1969. The products made, Novolen 1300 series, were based on high molecular mass total work up polymers (i.e., containing atactic PP and catalyst residues) having reduced stereoregularity. Today, such grades still find niche markets, although they are vulnerable to competition from random copolymers. Production is to be phased out shortly.

BASF also uses their process with a cheaper second-generation catalyst $TiCl_3/AlEt_2Cl$, which then requires an additional dry-powder dechlorination stage.

Amoco – Chisso Stirred-Bed Process. Collaboration between Amoco and Chisso resulted in joint licensing arrangements from 1985. This process uses a horizontally stirred reactor, Figure 28, instead of the vertical helical agitator of the BASF process. Condensed recycled monomer sprayed into the top of the reactor provides cooling, while uncondensed monomer and hydrogen injected into the base maintain the gas composition. Figure 28 also includes a fluidized-bed deactivation system for use with second-generation, chlorine-rich catalysts. Amoco – Chisso claim that their reactor achieves some degree of plug flow, roughly equivalent to that of 2 – 3 fully back mixed reactors in series [183].

Figure 28. Amoco – Chisso gas-phase process

a) Horizontal reactor; b) Fluidized-bed deactivation; c) Compressor; d) Condenser; e) Hold/separator tank

Unipol – Shell Fluidized-Bed Process [184]. The Unipol – Shell plants, commissioned in 1986, combine technologies from Union Carbide and Shell. Most conspicuous in this process, Figure 29, is the tall fluidized-bed reactor with its expanded upper section to reduce gas velocity and powder entrainment. Continuous feeds of catalyst components, comonomer, if any, hydrogen, and propene are thoroughly mixed in the dense-phase fluidized bed of powder. A large cooler in the gas recirculation loop removes all the reaction heat from the considerable gas flow. In this system the fluidized bed is said to behave as a fully back mixed reactor, without undue separation of coarse particles. No mechanical agitation is needed. Reaction conditions are reported as < 88 °C and < 4 MPa.

Figure 29. UCC/Shell – Unipol fluidized-bed process

a) Primary fluidized bed; b) Copolymer fluidized bed; c) Compressors; d) Coolers; e), f) Discharge cyclones; g) Purge

Product powder and associated gas are discharged from just above the distributor plate by timed valves into a cyclone separator (e) and then directly to a purge vessel (g) to remove residual monomer. Neither catalyst removal nor atactic polymer extraction is necessary with the modern Shell catalysts used in the Unipol process.

2.5.7. *Copolymerization*

Copolymers of propene with other α-olefins account for ca. 30 % of all PP sales. There are two distinct classes of copolymer having different application areas. Random copolymers, obtained by copolymerizing mixtures of propene and other α-olefins have lower melting points and improved clarity. Impact (block) copolymers, made in a two-stage polymerization process, are high-impact-strength grades that contain dispersed propene – ethylene elastomers.

2.5.7.1. *Random Copolymerization*

Random copolymers are made in the same way as homopolymers, but a mixture of propene and the comonomer is used in place of pure propene. Usually, polymers containing 2 – 6 wt % of combined ethylene cover most applications. Sometimes the resulting copolymers are referred to as “statistical” because heterogeneous Ziegler catalysts rarely yield truly random copolymers [157] with mixed feeds of monomers. 1-Butene can also be used, especially as a termonomer along with ethylene. The higher α-olefins are more expensive and less reactive than propene and can complicate the monomer recycle stage. However, attractive product properties are stimulating manufacture [185], [186].

In the case of suspension polymerization, either in hydrocarbon diluent or in bulk, significant amounts of soluble byproducts add to handling difficulties due to viscosity increases at higher comonomer contents. Drying temperatures must be reduced because of the lower softening point and more cohesive nature of the particles.

Gas-phase systems, especially those having some degree of mechanical agitation, are less adversely affected, though maximum temperatures still need careful control.

Random copolymers often find use in food packaging (see Section Copolymers), where the polymer must not contain high proportions of extractable material. Clarity improves and melting points fall as comonomer and solubles increase. A compromise is reached at about 3 wt % of ethylene. Changes to catalyst and polymerization techniques can raise this by securing a more uniform disruption of the isotactic sequences, which in turn encourages formation of the lower melting γ- crystallites [187].

2.5.7.2. *Impact (Block) Copolymerization [188], [189]*

Impact copolymerization is regarded as the lowest cost process for making toughened PP. It can be visualized as a method for producing an intimate blend of PP homopolymer with a toughening ethylene – propene elastomer. Approximately 10 – 20 wt % of this elastomer suffices for most applications, though the recent availability of products containing 30 – 40 wt % will expand their use.

The minimum requirement for block copolymerization is a two-stage process. In one stage homopolymer is prepared by any of the methods described in Sections Suspension Homopolymerization (Early Diluent Processes), Bulk Polymerization in Liquid Propene, Solution Polymerization, Spheripol Process , Hypol Process, Gas-Phase Processes. The other stage uses a mixed monomer feed of ethylene and propene to produce a largely amorphous, elastomeric phase within the polymer particles. Many other more complex configurations have claimed to be advantageous for certain products, but two stages are generally adequate [188], [189].

Homopolymer, or a very low ethylene copolymer, is always made in the first reactor because the elastomer fragments catalyst particles in diluent systems and produces sticky products in gas-phase reactors. This first stage of reaction, using propene and hydrogen as molecular mass controller, is indistinguishable from conventional homopolymerization. In batch slurry systems, propene is metered into a reactor until the amount of polymer formed is 80 – 90 % of the intended final make. The remaining 10 – 20 % is made in the second stage as follows. Normally the propene concentration is allowed to fall, by continued polymerization, to a predetermined value before introducing ethylene, propene, and possibly hydrogen. No further catalyst is needed for the second stage, and the reaction temperature might be lowered to reduce the amount of soluble polymer diffusing out of the particles. The high reactivity of ethylene promotes rapid copolymerization in a more exothermic reaction. Venting and polymer isolation follow the procedure already described in Section Suspension Homopolymerization (Early Diluent Processes), but filtration and atactic polymer separation are more difficult because of additional amounts of viscous soluble copolymer.

Gas-phase systems using modern catalysts avoid much of this difficulty. Figure 27 shows a typical BASF continuous process using two stirred reactors for making impact copolymers [182]. Active polymer and gas from the first reactor discharge directly into the copolymerizer, operated at 1 – 2 MPa lower pressure and lower temperature. Normally, the propene/ethylene/hydrogen ratio is adjusted such that the rubbery copolymer made in this reactor contains 40 – 60 wt % ethylene, depending on the particular grade. This gas composition is not readily condensed with cooling water alone, so a compression stage is added to liquify some of the recycled gas returned to the reactor base. Copolymer powder, with its associated carrier gas, discharges into the low-pressure cyclone separator (g), which passes this carrier gas to recompression for return to the copolymerizer. Residual monomer in the copolymer is removed in a combined purging and deactivation vessel (h) before conveying powder into silos for extrusion.

Analogous gas-phase techniques are used by other manufacturers. Amoco – Chisso (see Fig. 28) add a second horizontal stirred reactor when making impact copolymers, and El Paso also add a similar polymerizer after their bulk first stage. Unipol – Shell introduce a second, but smaller, fluidized bed (Fig. 29), operating at ca. 1.5 MPa, for their impact copolymers, thus taking advantage of enhanced copolymerization activity. Sumitomo's new process also uses two fluidized beds. Himont (Fig. 26) and Mitsui Petrochemical retain their normal bulk polymerization for the first, homopolymerization step, but use gas-phase copolymerization in a fluidized bed for producing impact copolymers. Such dry powder reactions overcome the problems arising from extraction of soluble copolymer species in liquid-based processes. At the same time, copolymer diffusion to the surface should be reduced by the lower degree of swelling in dry powder systems.

While copolymers containing 40 %, or more, of elastomer can be handled satisfactorily in plant processes, their cohesiveness calls for more care than with homopolymers. Himont patents suggest that their fluidized-bed technology recognizes this aspect. Overall, there is complete unanimity that a gas-phase copolymerization stage is preferred for this class of copolymer in modern plant.

2.5.8. *Product Finishing*

Considerable capital is involved in the finishing areas of all plants after the dry powder stage. The great majority of this powder is extruded with a variety of additives, pelletized, tested, and then stored in various packages for sale. Direct sale of suitably stabilized reactor powder circumvents some, but not all, of these costs.

Extrusion and Pelletization. Proprietary equipment from specialist manufacturers will always be used for high-throughput plants operating at 5 – 20 t/h and 250 °C. In selecting extruders the following factors are relevant (in addition to costs): powder morphology, product MFI range, melt filtration needs, devolatalization, turn down ability (i.e., efficient operation at low rates), temperature control, mixing needs, and additive feeds. The types of extruder available include long, single-screw machines and two-stage systems in which powder is melted in a continuous high-speed mixer which discharges the melt into a short, pressure-generating extruder. Twin-screw machines with corotating and segmented screws are increasingly used for additional flexibility. Versatility and output can also be increased by installing a gear pump between the die plate and the discharge end of the screw in any of these systems.

Pelletization takes two forms. Extruded laces from the die plate are quenched in water to give rigid strands. High-speed cutters then chop the continuous strands into 2 –

5 mm lengths to produce so-called lace-cut pellets. In the other system, high-speed knives rotate against the extruder die plate to cut off short lengths of the molten extrudate. Either the insulated die plate is immersed in water, or the molten pellets are instantly solidified by being flung into a water ring quench zone to prevent cohesion. These die face cut granules are increasingly common in large plants.

Salable Powder. Densification is avoided entirely for those outlets willing to use suitably stabilized powder. Spherical particles, up to ca. 0.3 mm diameter, have been available for many years, but in most applications pellets are preferred because of their better housekeeping (spillages, dust, etc.), easier handling in standard systems, and absence of concern about possible dust explosions due to powder attrition. Emergence of coarse Spheripol powders from Himont, 1 – 5 mm diameter, should dispel some of these concerns provided adequate and nonseparating stabilization systems are established with mechanically robust coarse particles. This will entail some additional manufacturing costs, and perhaps more product constraints, but this expenditure should be less than that for capital and energy intensive extrusion and pelletization operations. Himont is constructing a PP plant in Brazil, due for completion in 1991, which is claimed to have no extrusion facilities. However, these have subsequently been installed.

Additive Incorporation. Extrusion provides an efficient and convenient way of incorporating antioxidants and other modifiers into polymers. Metered amounts are mixed with the main powder feed to the extruder and homogenized in the molten polymer. Good mixing is essential to prevent extrusion of unstabilized product at high temperature. Nitrogen blanketing is common practice. Highly specialized and low-tonnage formulations are either made on a separate plant having appropriately sized equipment, or the customer himself adds concentrates in the form of stabilizer master batches.

Liquid additives, such as some antistats, can be metered directly into the melt, given good subsequent homogenization in the extruder.

2.5.9. *Additives*

Stabilizers [190]. Like most hydrocarbons, PP must be protected against oxidation, particularly above 100 °C. The dominant reaction is chain scission by free-radical attack at the tertiary carbon atoms of the backbone. This generates hydroxyl and carbonyl groups, accompanied by yellow discoloration and brittleness. Incorporating radical scavengers considerably delays the onset of embrittlement and increase of the MFI. Antioxidants are always incorporated into PP before or during extrusion at manufacturing plants. Usually a peroxide decomposer, such as a phosphite, is introduced to improve melt stability, together with hindered phenols to confer long-term aging resistance. Typically, the amount of each of these additives is 0.05 – 0.2 wt %, but in more aggressive environments the levels might rise to 0.5 %, with thiodipropionate esters as peroxide decomposers. The choice of stabilizer is influenced by the application, for example, interaction with spin finishes [191], resistance to extraction by hot water, and regulatory constraints.

Traces of copper or cobalt powerfully accelerate thermal oxidation, especially at sustained temperatures above 60 °C. In these cases a chelating agent such as a bishydrazone is added [192].

Continuous outdoor exposure also requires protection from the damaging effects of UV radiation. The severity of embrittlement increases at high temperature and with rainfall in some polypropylenes. Atmospheric pollution can deposit protective layers on the surface. Ultraviolet-absorbing compounds, such as alkoxybenzophenones and hydroxybenzotriazoles for thick sections, and hindered amine light stabilizers (HALS) for films, provide protection at contents of 0.1 – 1.0 wt % [193]. Screening with some fine pigments or carbon black is effective, but restrictive on appearance.

Gamma radiation, used for packaged food and sterilization of medical equipment, degrades PP, causing embrittlement. The effects can be mitigated by the careful choice of stabilizer.

Antistats. The familiar static charges and resulting dust deposits on many plastics can be overcome in PP by incorporating 0.2 – 1.0 wt % of polar additives. Suitable materials, such as polyether fatty amide and fatty amine condensates and glyceryl monostearate reduce the surface resistivity from > 10^{13} to ca. 10^{7} Ω. The mechanism involves slow diffusion of the additive to the surface where it picks up atmospheric moisture. Hence, time and humidity are important. At 50 % RH most of the recommended additives are satisfactory, but at 30 % RH the fatty amine derivatives are advantageous. A few days storage at room temperature is sufficient to develop the conducting surface layer.

Compositions containing moderate amounts of conductive carbon black are also effective, as are small amounts of polyacetylenes. The latter, and the incorporation of small amounts of fine metallic wire, are too expensive for PP applications.

Antacids. Most of the earlier PP formulations contained 0.05 – 0.2 wt % of calcium stearate to prevent traces of acidic catalyst residues from corroding customers' equipment. It behaves as a mild slip agent and suppresses attack of HCl on certain antioxidants. Zinc, magnesium, and sodium stearates have also been used, and more recently synthetic hydrotalcite (a hydrated magnesium aluminum hydroxycarbonate). Lower levels of such additives are still widely used.

Slip and antiblock agents are mainly used in film production where high-speed handling requires a controlled reduction in frictional forces. 0.1 – 0.5 wt % of oleamide, erucamide, glyceryl monostearate, etc., usually suffices. Fine, spherical particles of silica incorporated at the pelletization stage prevent layers of film adhering to each other during storage.

Crystallization Nucleants. Although pure PP has a final melting point of 176 °C, the melt supercools by 50 – 60 °C before crystallization sets in at ca. 115 °C. Small amounts of certain additives [194] nucleate the melt, raising the crystallization temperature by 10 – 15 °C. Smaller spherulites result, sometimes having different structures. Advantages of nucleated grades include shorter injection molding cycles, higher moduli, greater transparency, and higher heat distortion temperatures. Suitable additives include dibenzylidene sorbitol and substituted variants, di-*tert*-butylbenzoate salts, sodium benzoate, finely divided talc, sodium diaryl phosphates, and some pthalocyanine pigments. These materials are somewhat selective in their effects, i.e., some are particularly good for transparency improvement, but less effective for modulus enhancement. Careful balancing of the overall additives recipe is also essential because both adverse and beneficial interactions occur between some of the components [195].

2.6. Compounding

Compounding includes incorporating mineral fillers, glass fibers, elastomers, flame retardants, pigments, and carbon black. It is a specialized operation dealing with relatively short run lengths in specified compounding extruders or mixers. For this reason, and for concern about cross contaminating unmodified PP grades, compounding plants usually operate separately from main PP production plants.

Substantial property enhancements enable polypropylene-based products to compete in quite demanding areas where unmodified PP would be inadequate (see Table 18). Examples include tough front and rear bumpers for cars, rigid coupled glass compositions for washing machine tubs, dense grades for outdoor garden furniture, and temperature-resistant compositions for car under hood applications. Long-fiber-reinforced PP secures further increases in toughness and stiffness over short-glass-fiber compounds [196]. Fibers with a minimum length of between 0.8 and 3 mm, depending on the coupling between matrix and fiber, are likely to be satisfactory. These form an interlocking skeletal structure which dissipates the impact energy over a large area of the molding.

Table 18. PP compounds — property enhancement

Property	Homopolymer	Impact copolymer	Compound	Composition
Toughness, kJ/m^2 (N Izod, 0 °C)	3.0	10.0	> 50	rubber + filler (car spoilers)
Modulus, GPa	1.5	1.0	7.6	coupled glass
	1.5	1.0	2.7	chalk loaded
Heat distortion temperature	105	90	160	coupled glass
(0.45 MPa), °C	105	90	130	talc filled (heater casings)

The combination of lower production rates, specialized equipment, and dense additives mean that PP compounds are always more expensive than natural grades.

2.7. Properties

2.7.1. *Homopolymer*

Basic mechanical properties are largely influenced by molecular mass and molecular mass distribution (MMD), chain stereoregularity, and processing conditions, which introduce orientation, strain, etc. Various additive packages must be tailored to the application to achieve good and durable performance.

Molecular Mass. At low shear rates melt viscosities are proportional to the 3.4 power of the weight-average molecular mass. At the higher shear rates found with most processing equipment, the dependence is still greater than a power of 2 because much chain entanglement still exists. As a result of this sensitivity, and the direct relevance to processing, the melt flow index (MFI) is always used to describe the viscosity characteristics of each polymer grade. The dependence of melt viscosity on shear rate is also related to MMD as a result of the strong influence of very long chains. Hence MFI is often measured at two different shear rates to give some idea of MMD. Increasing

importance is being attached to a more comprehensive rheological characterization [197], [198].

A typical, medium-flow polymer has an MFI (230 °C/2.16 kg) value of 3 dg/min, corresponding to a M_w of 460 000 and M_n of 54 000. The practical grade range of 0.3 – 50 MFI covers applications from sheet and pipe extrusion to high-speed fiber spinning.

Heterogeneous Ziegler – Natta catalysts yield broad MMD polymers having M_w/M_n of 5 – 10, the lower values being associated with the more recent Solvay and supported catalysts. Very narrow MMDs are still made by preferentially cleaving long chains in an extruder, usually with the assistance of organic peroxides. Such grades, commonly referred to as controlled rheology (CR) polymers, reduce extrusion and molding orientation caused by high molecular mass species with their long relaxation times [199]. Note that reworked polymer is likely to have a higher MFI and a correspondingly narrower MMD than the starting material.

Stereoregularity. Very high stereoregularity is now achievable with modern catalysts, even without removing any soluble byproduct. In some applications processing is helped by a small lowering (detuning) of the isotactic index. This is readily achieved by minor changes to the polymerization recipe, and by introducing small amounts of copolymerized ethylene.

Metallocene-Based PP. An expanded range of products is imminent following the encouraging metallocene developments. Further pilot trials and customer assessment of processing, product, and economics is needed before precise definition is possible. The advantages already seen include higher extrusion rates for films and fibers, enhanced clarity, absence of oligomers, superior property balances, and the ability to control further melting point reductions by copolymerization without significantly increasing the low level of xylene-soluble material.

Other Properties. Table 19 lists the properties of several polymers measured by standard procedures, with some copolymer data included for comparison. Care must be taken in translating these exact values to fabricated products because properties are dependent on built in stress and orientation. Increasing the molecular mass, i.e., lowering MFI, raises toughness somewhat, but the modulus and hardness decrease with the lower crystallinity.

Table 19. Mechanical and thermal properties of PP Origin "Propathene" (with permission of ICI Chemicals & Polymers)

Property	Method	Temperature	Homopolymer				Impact copolymer		Random copolymer
			GSE 16	GWM 22	LYM42	LZM 55/52	GWM 101	GWM 213	LXF 301

50 Hz	0.00015
1 kHz	0.0002
1 MHz	0.00015

The final melting point of commercial PP lies in the range 160 – 170 °C, with purified polymer reaching 176 °C. However the safe upper working temperature limit should be 100 – 120 °C, depending on the stress, with short excursions up to 140 °C being permissible. This comfortably extends the upper operating range available with high-density polyethylene by ca. 20 °C, which has a similar room temperature modulus.

Favorable long-term creep characteristics under load permit useful increases in the stacking height of PP crates or other pelletized containers. The repose angle of PP moldings on wood or canvas, unpredictably 30 % higher than for HD polyethylene, is allegedly a useful stabilizing feature in mechanical conveyors.

The crystalline and nonpolar nature of PP confers good resistance to a wide range of aqueous and polar media, including emulsifier solutions with their strong stress cracking abilities. Powerful oxidizing agents and highly aromatic or chlorinated solvents are too aggressive for safe storage in PP containers.

The ease with which homopolymers can be drawn into high strength structures has been heavily exploited in the fiber and film industries (see Section Fibers and Flat Yarns).

2.7.2. *Copolymers*

Random Copolymers. Incorporating 2 – 7 wt % of ethylene into the main chain lowers the overall crystallinity, gives a broader softening range with reduced melting points (Figs. 30 A, 30 B), increases the fraction of soluble polymer, and improves transparency and surface gloss. These changes are dependent on the amount of comonomer and its distribution along the chain. Table 19 shows how the modulus decreases for a random copolymer containing ca. 3 wt % of combined ethylene.

Figure 30. A) DSC heating endotherm; B) DSC cooling exotherm

Courtesy of the "Propathene" Business, ICI Chemicals & Polymers

Several applications take advantage of the lower melting point to make thermoweldable film. Ideally, it would be useful to have a low melting range without undue increases in the proportion of xylene-soluble residues. This is claimed to be possible with butene copolymers, perhaps because the solubles are produced at semi-exposed catalyst sites more easily accesible to ethylene [186]. Some advantages are also claimed for propene – ethylene – butene terpolymers [180], [185]. Butene helps the development of low-melting γ-triclinic crystallites. Random copolymers are somewhat tougher than homopolymers, and do not exhibit the familiar stress-whitening behavior of the tougher copolymer impact grades.

Impact Copolymers. Section Impact (Block) Copolymerization describes block copolymerization systems for making high impact strength grades of PP. These are often referred to as block copolymers, toughened polypropylene, or more pedantically heterophasic copolymers [180].

Essentially, these products are best viewed as an intimate dispersion of elastomer in a PP matrix. The particulate rubber phase confers good toughness, while the homopolymer matrix is responsible for retaining good high-temperature performance and adequate stiffness. In this respect they are far superior to random copolymers, and become the first choice when impact strength and rigidity are called for. In extruded pellets or molded articles the rubbery copolymer phase is well distributed in the form of droplets 1 – 5 µm in diameter. Such a structure (Fig. 31) is produced during melting and recrystallization. Powder direct from the reactor has elastomer permeating throughout the particle in a more continuous form. Many of the complex interactions which control the stability of this phase structure and the resulting toughness, await further study, but current views are very well discussed by VAN DER VEN [189].

Figure 31. Electron micrograph of high impact copolymer molding after hexane surface wash

Toughness, stiffness, and softening points are given in Table 19 for two impact copolymers containing ca. 10 and 20 % of elastomer. Gas-phase polymerization systems are able to increase the rubber content to 40 %, but the products are not available in large commercial quantities at present. These impact copolymers naturally contain more soluble polymer than homopolymer, and this second phase reduces the translucency. Severe deformation causes some whitening or blushing [200] in the stressed regions, particularly in very high impact grades. In other respects the rules relating processing and properties to MFI, nucleation, controlled rheology, stabilization, etc., are the same as for homopolymer.

2.7.3. *Elastomer Blends with Polypropylene*

Originally, PP was toughened by blending with ca. 10 wt % of polyisobutylene (PIB) elastomer. In some situations the same technique is used today, with ethylene – propene rubber (EPR) or ethylene – propene – diene rubber (EPDM) replacing PIB.

As rubbers are incompatible with PP, considerable mechanical work is necessary to secure the vital fine dispersion of elastomer. Good blending also requires a reasonable viscosity match between the two components. Common practice is to use a two-stage process in which the elastomer is first compounded with PP to give a 50 – 70 wt % masterbatch of the rubber as free flowing granules. Such masterbatches can be purchased at extra cost. Good mixing devices are essential for the final compounding step with PP. Twin-screw extruders or high-speed mixing devices perform satisfactorily.

Well-prepared blends have physical property combinations only just short of those of directly polymerized impact copolymers. However, the latter are generally preferred on account of consistency and grade versatility. Elastomer blending is also part of the broad spectrum of compounds referred to in Section Compounding. Here they are used to uprate the toughness of homopolymer and impact copolymers in these complex formulations. Some manufacturers also introduce HD polyethylene, in addition to rubber, to secure further toughness improvements. In these cases, electron microscopy reveals that in well-dispersed systems the polyethylene is always located inside and towards the center of these rubber droplets. This encapsulation of PE makes it behave more like rubber towards the matrix, thereby increasing toughness at the expense of modulus in such ternary blends.

2.8. Uses

Polypropylene is readily processed in conventional equipment used for other thermoplastics. Injection molding, commonly using screw-type reciprocating machines, accounts for 40 – 50 % of all applications. Extrusion processes account for the remainder with domination by fiber and film.

A more detailed picture is obtained by analysing the North American 1996 sales data (in 10^3 t/a) listed in the following [202] :

2.8.1. *Injection Molding*

An exceptionally wide range of injection-molded products stems from the rigidity, toughness, and chemical and temperature resistance of PP. Examples include automotive trim and ventilation components, bottle crates, industrial containers, washing machine tops and tubs, kitchenware, tool handles, domestic waste systems, and small boat hulls. Such a variety of articles requires careful grade selection according to the required impact strength of the product and the melt flow constraints of the processing equipment. An MFI (230 °C/2.16 kg) range of 2 – 20 dg/min meets most needs. Increasing the MFI not only assists mold filling and reduces cycle times, but it helps manufacture of complex moldings having high flow ratio geometries (flow ratio is the ratio of longest path to the section thickness). The inevitable fall in impact strength at high MFI can be recouped, in some cases, by moving from homopolymer to impact copolymer grades.

While molding conditions vary with the size and complexity of the article, the following machine settings will cover most products [199]:

Melt temperature:	230 – 275 °C
Injection pressure:	55 – 100 MPa
Mold temperature:	40 – 80 °C, lower still for thin walled items

The low moisture absorption of PP largely dispenses with any need to dry granular feedstock. Neither do gaseous or carbonaceous decomposition products form in extruder dead spots. Instead, polymer remaining there becomes progressively more fluid through chain scission. Machine shot weight capacities normally refer to performance with polystyrene, i.e., the polystyrene yardstick figure. The lower melt density of PP (0.75 g/cm^3) lowers the machine's weight capacity by ca. 25 % when molding PP. Plasticizing capacity is slightly greater than for polyethylene, but is lower than for amorphous polystyrene. Machine outputs with PP benefit from the ability to eject moldings

at higher temperatures than with their lower softening counterparts.

Linear post-molding shrinkage of PP is 1 – 2 %, of which 85 % occurs within the first 24 h. Distortion in molded products reflects internal stress caused by nonuniform cooling and polymer orientation. The latter is especially pronounced in surface skins where the viscous melt stretches as it is pulled along by the advancing melt front adjacent to cool walls. Controlled rheology (CR) polymer, containing fewer of the orientation-prone long chains, reduces this type of warping [199].

An important practical aspect of PP concerns its ability to form strong integral hinges, such as in a lidded box, where the lid is permanently attached to the base by a thin web of polymer along the whole of one edge (Fig. 32). This web, about 0.25 – 0.6 mm thick, can be produced directly in the molding process or by post forming operations. An initial flexing of the hinge while slightly warm induces the correct molecular orientation to permit repeated opening, even at subzero temperatures. In the laboratory, such hinges have withstood 23×10^6 flexes without failure [203].

Figure 32. Integral hinge

Courtesy of the "Propathene" Business, ICI Chemicals & Polymers

Various types of structural foamed moldings can be produced having a cellular core sandwiched between solid integral skins giving an overall density in the range 600 – 800 kg/m^3 [204]. These lightweight, but rigid parts can vary in size from a paint brush handle to a sack pallet or car body panel. Foaming results from using a tumble-blended feedstock of granules and a chemical blowing agent. Alternatively, high-pressure nitrogen can be injected into the melt. Molding techniques are altered to achieve extremely rapid polymer injection rates into the mold. This prevents premature foaming before the solid skin forms. Foaming in the core arises by allowing the melt pressure to fall rather than maintain the customary pressure hold to keep the mold full.

Four alternative foam processes exist:

1. In the ICI sandwich molding process, different polymers are used for the skin and core by using two separate injection barrels. As the skin is unfoamed, high-quality surfaces result.
2. In the Varitherm Process (BASF, Krauss Maffei), improved surface finish is achieved by using a hot mold (100 – 120 °C) followed by rapid cooling after a short shot of the melt (i.e., an injection of polymer insufficient to fill the mold).
3. In the counterpressure method the mold is pressurized prior to filling to prevent degassing at the melt front.
4. In hollow section molding (e.g., CINPRES) nitrogen is injected in a continuous stream into the mold at the same time as the polymer melt. Under appropriate conditions, hollow or ribbed moldings are produced when gas flows preferentially down thick, hot sections of the molding. This technique is of increasing interest.

2.8.2. *Blow Molding*

The extrusion blow molding process for PP copies that already well established for low- and high-density polyethylene. However, application to PP has been slow while suitably viscous and tough polymers were developed at attractive prices. At present, the important areas are smaller packaging containers which take advantage of good transparency, good form stability up to 140 °C for hot filling or sterilization, and greater freedom from environmental stress cracking with aggressive products. Brake fluid reservoirs exemplify this. Very large containers are dominated by high-density polyethylene.

Extrusion blow molding employs two linked processes [205] in which an extruded molten parison is transferred to a mold for inflation with low-pressure air at 0.4 – 1.0 MPa. High molecular mass polymer, MFI(230 °C/2.16 kg) 0.4 – 2.0 dg/min, combined with low melt temperatures at the die of 200 – 210 °C, provide a suitably stiff melt. If the melt stress in a heavy PP parison exceeds ca. 20 kPa, then the resulting tension thinning will be troublesome as regards parison stability and uniform wall thickness.

Injection blow molding replaces the extruded parison with an injection-molded preform. Blowing takes place in a second mold which maintains the high-definition neck of the preform. This process eliminates scrap and makes it easier to produce wide mouth containers having improved dimensional accuracy and appearance.

Injection stretch blow molding is a further refinement which introduces a plunger stretching stage to elongate a conditioned parison or preform just before the final blow (see ⟶ Plastics, Processing). Better mechanical properties and enhanced transparency stem from partial orientation. This technique is sometimes referred to as the melt phase process.

In stretch blow molding, the extruded or molded preform is carefully conditioned to just below the polymer melting point before stretching. Axial stretching of the preform with simultaneous or almost immediate blowing in the mold produces a very high quality container. Correctly carried out, this process secures increased rigidity and toughness, high transparancies, and reduced permeabilities as a direct result of significant amounts of orientation. The more complex technique increases capital and operating costs, but it is of growing interest [206] and is already being applied extensively to biaxially oriented PETP bottles.

Coextruded parisons can be used as precursers for blow molding when special barrier properties are required [207]. In particular, a central layer of ethylene vinyl alcohol copolymer (EVOH) to reduce oxygen diffusion, combined with moisture protective outer layers of propene – ethylene random copolymer, give containers suitable for storing oxygen-sensitive food products.

2.8.3. *Fibers and Flat Yarns*

Very large amounts of polypropylene homopolymers are used for fiber manufacture in Europe and the United States. These applications exploit the wide range of physical forms, including increasing amounts of versatile nonwoven fabrics [208-210]. Monoaxial orientation can be applied to conventional spinneret yarns, as with polyamides and polyesters, and to flat tapes made from extruded film. These differ in the following respects (Table 20).

Table 20. Polypropylene fiber processes

Process	Filament count, tex *	Product
Long spin	0.2 – 3.0	high-tenacity monofilament; drawing integral or separate; high output
BCF yarn	0.2 – 2.0	special case of long spin making only bulked continuous fiber
Spunbonded	0.2 – 2.0	venturi haul off; no 2nd stage draw. bonded mat output
Shortspin	0.2 – 40	compact unit; tow stretched and cut in line for staple
Melt blown	0.002 – 0.02	low orientation, very fine fiber; only bonded mat output
Fibrillated yarn	110 – 500	oriented slit film; fibrillated for baler twine, rope, etc.
Weaving tape	ca. 110	nonfibrillated slit film for carpet backing, sacks, etc.
Strapping tape	500 – 1000	thick, oriented tape as a steel alternative

* tex = weight in grams of 1000 m of yarn; equivalent cylindrical fiber diameter in $\mu m = 37\sqrt{tex}$.

Spinneret Type Yarns. Here melt is extruded through a die plate perforated by many small holes to generate individual thread lines. In the long spin process [211] (see ⟶ Fibers, 4. Synthetic Organic – Staple Fiber Production Process), which has integral spinning and finishing stages as well as out of line drawing options, there may be 50 – 250 holes per spinneret. An air cooling gap of 2 – 5 m is needed between the die plate and the wind-up roll. Line speeds up to 1000 m/min at the spinning stage, increasing to 3000 m/min during solid drawing over hot rolls, call for complex and expensive haul off, drawing, and wind-up sections. Product may be packed off as continuous yarn, tow, or staple. Suitable polymers have MFI(230 °C/2.16 kg) in the range 12 – 25 dg/min, with narrower molecular mass distribution grades offering some advantage with such high rates of melt draw. These are high-throughput plants, best suited to long runs of a single grade of product.

In a variation of this technique [212], the integrated spunbonded process (see ⟶ Fibers, 3. General Production Technology – Process Technologies for Spunbonded Nonwovens), yields a continuous bonded mat of partially oriented yarn as a consequence of some draw in the venturi type haul off operating at up to 5000 m/min. There is no further drawing as the fiber is collected as a mat on the take-off belt for conversion into nonwoven fabrics. These are used, for example, in geotextiles, furnishings, carpet backing, etc. The balance of drawdown rate and orientation in this process is influenced by the polymer molecular mass distribution.

Figure 33 depicts a compact shortspin process for staple production using a die containing ca. 40 000 holes. Cooling air jets freeze the melt within about 20 mm so that Godet haul off rolls can be placed only 1 m away from the die. Orientation is achieved by the in-line stretching of this tow in an air oven, followed by chopping in line to produce staple [207]. Broad molecular mass distribution polymers give the necessary melt strength, while MFI(230 °C/2.16 kg) requirements increase from 7 to 20 dg/min as the filaments become finer. These find use in geotextiles, carpet face fiber, and diaper cover stock applications. A useful feature of PP fabrics made from fine fibers is the ability of underwear garments to reduce claminess by transferring moisture away from the skin to an outer absorbent layer. Polypropylene based fabrics are also used for sports clothing and socks, but the low melting point of PP calls for special attention to the heat setting of the average domestic iron.

Figure 33. Shortspin process

In the third, and most recent production process (Fig. 34), air is blown through a very fluid polymer melt maintained at high temperature to assist chain scission in the spinning process itself [212], [213]. Polymer MFI(230 °C/2.16 kg) at the nozzle can range from 35 to 300 dg/min or higher. The specially designed die, having a row of nozzles along its width, sprays a stream of short, low-orientation fibers onto a moving belt where they are bonded together and wound onto a roll. This process produces nonwoven fabrics which are of increasing importance for industrial wipes and surgical wrap, and for a variety of filtration applications, such as face masks made from bonded mats of very fine fibers.

Flat Yarns [214] (see also ⟶ Fibers, 4. Synthetic Organic – Polyolefin Film Yarns and Split Yarns). In this process (Fig. 35), extruded film is the basis of a cheap and different type of product to that achievable with filament-based yarns. Melt from a conventional slot die is rapidly quenched with cold water or water- cooled steel rolls to give low- crystallinity film, 50 – 250 µm thick. Razor blade type knives then slit this broad film into strips 5 – 20 mm wide, which are oriented in a hot air oven at 120 – 180 °C by drawing between Godet rolls at ratios in the range 5 : 1 to 10 : 1. Both film thickness and width diminish in this operation by approximately the square root of the draw ratio.

Fibrillated Tape (see also ⟶ Fibers, 4. Synthetic Organic – Polyolefin Film Yarns and Split Yarns). While flat yarns are quite strong in the direction of draw, they are very weak in the transverse direction. With normal homopolymer, simply twisting high-draw-ratio tape induces spontaneous fibrillation. A web of irregular fine fibers is formed as the film splits down its length. The resulting product resembles a coarse sisal twine, for which it is a good substitute. Such fibrillated yarns can be tailored to specific applications by controlling draw ratios, thickness, and polymer. Nowadays, pin fibrillation, in which a corotating spiked roll contacts the film just after slitting, offers more precise control over this step. The products are familiar as baler twine, string, and some ropes.

Weaving Tapes. High strength tapes, without fibrillation, are made by controlling extrusion, orientation, and polymer type. Introduction of finely divided chalk, together with some polyethylene, usually as the chalk masterbatch, is particularly effective in reducing splitting. Impact copolymers are a more expensive, and rarely used, alternative to homopolymer for this application.

Both tapes and fibers contain residual stress from the extrusion and orientation processes. This results in linear shrinkages of up to 8 % immediately after manufacture, but after storage for a few days at room temperature the value falls to about 2.5 %. For those applications, such as weaving tapes for carpet backing, where zero shrinkage is often needed, a heat setting stage is essential. Out-of-line storage of the tapes on bobbins at 130 – 135 °C for several hours often suffices.

Thick, 0.3 – 0.9 mm, oriented tapes are established alternatives to steel bands in many strapping applications. They are generally made by the water quench process operating at draw ratios of 9 – 10. Thicker tapes are made from foil or individually extruded film tapes. High molecular mass, MFI(230 °C/2.16 kg) 0.4 – 2.0 dg/min, homopolymers and block copolymers with added chalk and polyethylene largely suppress fibrillation. A further precaution here is to emboss the finished tape with a diamond pattern. A useful aspect of PP strapping tapes is their higher elongation and elastic recovery which helps them to remain tight on packages prone to shrink or settle.

2.8.4. *Film*

Packaging film is an important outlet for PP, accounting for about one sixth of polymer sales in Europe, and rather more in Japan (see Section Compounding). By far the major proportion of this is biaxially oriented PP (BOPP), an established replacement for regenerated cellulose. Although the equipment needed for orientation is complex and expensive, it secures superior physical properties.

Good clarity in unoriented film is dependent on very rapid quenching of the melt to reduce spherulite size. The chill roll extrusion process (see ⟶ Films – Extrusion) for making 30 – 250 µm film extrudes a mobile, hot melt from a slot die onto water-cooled, highly polished steel rolls. Extrusion temperatures of 240 – 270 °C combined with an MFI(230 °C/2.16 kg) of about 7 dg/min minimize surface irregularities in the melt. Random copolymers containing 2 – 3 wt % of combined ethylene enhance toughness, clarity, and gloss, with some loss of modulus. These soft-feel transparent films are used as textile packages, bakery wraps, and document sleaves at thicker gauges.

Tubular quenched (TQ) film made in a downwardly extruded bubble (Fig. 36) uses some external water cooling which achieves reasonable clarity in film for packaging. In contrast, the less common tubular film from the air- cooled upwardly extruded bubble is more hazy, but finds use in the production of weaving tapes (Section Fibers and Flat Yarns). For most film applications, slip and antiblock additives are needed.

Figure 36. Tubular quenching process

a) Melt from extruder; b) Die; c) Air ring; d) Air flow; e) Film; f) Water quench weir; g) Cooling skirt; h) Nip rolls; i) Dewatering, slitting, wind up etc.

Biaxially oriented polypropylene (BOPP) film [215], [216], typically 12 – 40 µm thick, has excellent transparency, toughness, and stiffness, and is widely used in cigarette and biscuit packages, potato chip bags, and carton overwrap. Film modulus is three times that of the unoriented cast product. These complex film manufacturing plants are usually proprietary systems based either on a bubble process, or on a flat die (stenter) process. In the bubble process (Fig. 37), thick cast tube is reheated and then blown into a bubble with simultaneous stretching in the transverse and machine directions to produce a balanced film. The stenter process (see ⟶ Films – Biaxial Stretching) uses thick cast sheet which is reheated and conditioned for drawing. Longitudinal and lateral stretching are performed separately and can be adjusted to secure the required orientation balance. The typical area draw in these processes is 30 : 1 to 50 : 1.

Figure 37. BOPP bubble process

a) Cast tube; b), c) Stretching heaters; d) Bubble guides; f) Air ring; g) Wind up, slitting, etc.

It is impossible to heat seal such highly oriented material because unacceptable shrinkage then occurs. Low-melting surface coatings overcome the problem by reducing the sealing temperature to a level which the films can safely withstand. Suitable materials are vinylidene chloride copolymers, polyethylene, poly(1-butene), as well as butene, propene, and ethylene co- and terpolymers. Some of these may be applied as aqueous emulsions, but common practice is to coextrude the low-melting polymer as an outer layer of the cast tube or sheet. After orientation, this layer can be less than 1 µm in thickness. These more compatible polyolefin coextruded coatings also simplify scrap recovery and recycling without fear of the coating instability inherent in halogenated polymers.

Polypropylene film, however made, is not receptive to printing inks and adhesives because of the low polarity. Mild surface oxidation by corona discharge treatment overcomes these problems.

2.8.5. *Foil and Sheet*

Slow heat transfer rates in sheet and thick foil call for extended cooling times at the extrusion stage. Foil, up to about 0.7 mm thick, can be made by the cast tube process (Section Film), but the more versatile three roll stack system (Fig. 38) is able to produce sheet with thicknesses of 0.3 – 15 mm. Recent techniques involving additional and larger diameter rolls extend this range to 40 mm. Thicker sheets are made by compression molding of granules or large molded slabs, and by injection – compression molding. This can make 2 m square slabs with thicknesses up to 240 mm. High molecular mass homo- and copolymer, MFI(230 °C/2.16 kg) ca. 0.3 – 1.0 dg/min, provide higher dimensional stability in slow- cooling, thick-section melts whose temperature at the die exit is ca. 210 °C. Higher flow grades with MFI(230 °C/2.16 kg) of up to 5 dg/min may be used for thin foil, depending on the available equipment.

Figure 38. Three roll stack extrusion

a) Extruder; b) Slot die; c) Polishing stack; d) Nip rolls; e) Wind up

Commercial sheets, normally up to 2 m wide provide stock for fabricating into welded tanks for storing corrosive liquids. They are also used as linings for steel and concrete containers, for ducting construction, and as an inert construction stock for chemical plant. It is possible to bond woven glass or polyester fabric to the heated surface for subsequent further strengthening using traditional glass fiber lamination techniques. Punched sheets can be biaxially oriented to generate heavy duty meshlike structures for geotextiles [217].

Thick sheet, as made, has a nonuniform structure across its thickness as a result of considerable differences in cooling rate.

2.8.6. *Extruded Pipe*

Compared with polyethylene, tubing applications for PP are quite small. However there are several areas where PP's increased resistance to aggressive media and its better performance at elevated temperatures are advantageous.

Extrusion at ca. 225 °C is straightforward; a central torpedo is used to make the hollow pipe [218]. Homogeneous melts require an extruder having a length-to-diameter ratio of 25 : 1 and a compression ratio of 4 : 1 to reduce the risk of trapping air in the extrudate. Pipe up to 300 mm outside diameter is generally vacuum sized in a water bath: semi-molten pipe passes through a finely perforated steel tube having vacuum applied to its external surface. Larger pipes are made by pressure sizing where nitrogen or air is injected via a small capillary into the torpedo to expand the pipe to the sizing die form. Both homopolymers and impact copolymers are used in the MFI(230 °C/2.16 kg) range 0.3 to 2.0 dg/min, increasing to 4.0 for drinking straws and ballpoint pen tubing.

Copolymers, providing superior impact strength with some flexibility, find use in domestic waste systems. Homopolymers have higher resistance to stress. It is essential to have a heavy duty stabilization system which will withstand extraction for applications involving aggressive and hot environments, such as chemical plants and effluent pipes. Manufacturers offer guidance [218] on polymer selection and pipe design conforming to the various pressure classes in BS 4991, and to BS 52 254 and BS 5255 for domestic waste pipes and fittings. Creep data are available [218] for pressure pipes predicting performance for up to 50 years.

Pipe jointing uses all the common techniques, with the exception of solvent welding. Ring seals with rubber inserts allow some movement in domestic waste pipes. Also used are flanged joints, hot plate butt welding, and socket fusion welding, the latter being optionally supplemented with hot-gas bead welding. Compression joints involving copper alloys should not be used at temperatures exceeding 60 °C because of reduced life expectancy.

2.9. Environmental Aspects

2.9.1. *Recycling*

The structure and properties of PP make it well suited to recycling operations. There is no fear about cross-linking, nor of complications with plasticizers or chlorine-rich species. Re-extruding PP usually lowers its molecular mass and narrows the molecular mass distribution, particularly in aged feedstock. This can be helpful in some applications that require enhanced flow. Adverse factors which must be assessed include some loss of strength from reprocessing/ageing, oxidation stability, discoloration, and contamination.

PP Manufacturers. Manufacturers usually produce small proportions of PP which do not meet their full quality requirements. Examples include deviations in MFI/MMD, antioxidant levels, copolymer characteristics, and gels. Provided these faults are within predetermined limits in the quality protocol, the material may be recycled in small proportions, sometimes with further corrective adjustments to the composition. This operation calls for additional work, and can reduce plant output by having to process the polymer twice. For this reason, and in those cases where recycle is not permitted or the deviations are too large, manufacturers either reclassify the product to a lower grade, or sell to an outside compounder for further reprocessing. This minimizes disturbances to continuous manufacturing processes.

A second source of much lower grade material, arises when manufacturing conditions are severely disturbed. This can be due to instrumental and human error, blockages, equipment failure, or extrusion disturbances. In these cases scrap can vary from substandard reactor powder to blocks of polymer from extruder dumps. External reprocessors convert such products into surprisingly useful materials by blending and recompounding. To them, the availability of essentially pure PP is the prime requirement.

Plastics Converters. Turning PP into moldings, pipe, film, etc., invariably involves some scrap production. Apart from substandard articles, there are sprues from moldings, edge trim from film and sheet, parison waste, and stamped sheet from thermoforming. These are recovered for recycling by the converter himself if the application allows, or more often by an outside compounder. In favorable situations involving long runs of a standard product, the converter segregates waste, grinds it, and then recycles it by blending small amounts with virgin feedstock when specifications permit. Occasionally there is an undemanding application which can accept large proportions of such regrind without difficulty. Storage and segregation problems are reduced when the converter simply collects his scrap together in the form of regrind for sale to a compounder.

The British Plastics Federation (BPF) estimates [219] that there are about 60 reprocessing companies in the United Kingdom handling at least 150 000 t/a of polymer. Forty three of these process an estimated 25 000 t/a of PP [220]. Only a few of these also process recovered scrap into molded products such as horticultural, highway, safety, and street furniture, which do not make excessive demands on polymer behavior. Included in the estimated figure are 15 000 t of recovered used battery cases and crates which can be converted into quite respectable compounds. Most reprocessors only handle single polymers, not mixtures. Their main supply sources are plastics converters and industrial or commercial establishments as suppliers of fairly well defined PP scrap [221].

Recycling PP After a Full Service Life. Nearly half the thermoplastics used in Europe are converted into packaging [222]. In the United Kingdom 13 % of this is based on PP, involving an estimated 142 000 t of polymer in 1988.

Polymers used in United Kingdom for packaging in 1988 (in 10^3 t) broke down as follows [222]:

Low-density polyethylene (LLDPE and LDPE)	510
High-density polyethylene	255

Polypropylene	142
Polystyrene	78
Poly(vinyl chloride)	68
Poly(ethylene terepthalate)	53
Expanded Polystyrene	21
Total	1127

Inevitably, much of this has only a short life before it ends up as waste in some form. Domestic waste contains 5 – 7 wt % (up to 20 % by volume) of such products [220], very little of which is currently recovered. Public concern about the environment naturally includes highly visible plastic litter, which is made unduly prominent by its low density and durability. This is an additional factor accelerating legislation for recovery of all types of packaging, including glass, metal, paper, as well as plastic [223-225].

In the case of PP, notable success rests with recycling old plastic bottle crates and battery boxes in Western Europe and the United States. This is mainly attributable to the ease with which large amounts of a clean single polymer can be collected without cross contamination from other plastics. Cooksons Plastics [226] and others [227], [228] have expanded on lead recovery to retrieve PP battery cases themselves. A mechanised sorting system has to separate stones, metal, wood, string, ebonite paper, and residual acid. The Cookson process involves crushing, several stages of washing, flotation, and screening followed by drying and extrusion. The final products include good-quality PP capable of being used in automotive products and for certain types of battery cases. Success here rests in quality upgrading by adding elastomer to enhance toughness, stabilizers, and antacid incorporation to recoup oxidative stability, and molecular mass tailoring with peroxides for specific applications. Hoechst [229] plan to collect plastic waste from scrap cars, household appliance industries, and presorted packaging waste. The 5000 t/a plant near Cologne should be in operation by mid-1992. ICI studies on scrap recycling from used PP crates stress the need to incorporate additional stabilizer in weathered products, and to allow for some reduction in impact strength for seven-year-old crates.

Recovery and reuse of mixed plastics is more difficult. The real need is to develop applications and fabrication processes for such comingled polymers, which are essentially incompatible and contaminated. Generally, they will be channeled into some massive products, such as posts, construction boards, and other bulky structures where resistance to water and decay is more important than high inherent strength. Some 20 different European schemes aim to make recycled plastic components as wood and concrete replacements for agricultural applications [223], [230]. Comingled scrap can be upgraded by blending with other recycled polymers to assist processing.

2.9.2. *Pyrolysis*

PP can be cracked to liquid hydrocarbons by thermal pyrolysis at 400 – 550 °C. In a recent process developed in Japan [231], zeolite catalysts enable this temperature to be reduced to 200 – 420 °C by using a two-stage heating process. Other polyolefins, such as polyethylene and polystyrene, and some chlorinated plastics can also be pyrolized to liquid products. Process cost estimates are $ 235 per ton of plastic, which yields 0.5 m^3 of gasoline, 0.5 m^3 of kerosene, and diesel products. Plants are expected to be built in Taiwan and Korea in 1991.

2.9.3. *Incineration*

Municipal waste is normally disposed of in landfill sites, with incineration being the next most important method [232]. As suitable landfill sites become rarer and more expensive, pressure is exerted to reduce waste volume either by incineration or by scrap recovery.

Modern incineration technology, with energy recovery in the form of electricity generation, can take advantage of the high calorific value of thermoplastics. Municipal waste calorific values average 10 kJ/g, compared with 30 – 35 kJ/g for coal. At 44 kJ/g, PP and other polyolefins have the same calorific value as fuel oil. Moreover, PP has an exceptionally low sulfur content, making it a very clean fuel with no apprehensions about toxic flue-gas emissions. These incineration plants are costly to build. Even after allowing for the sale of electricity, the net disposal cost in the United States is estimated at 40 – 70 $/t of processed waste [224]. Special burners have been developed to handle atactic and isotactic waste PP feedstock, but more profitable outlets are now available.

2.9.4. *Environmental Interactions*

Overall PP manufacture, like any other product, involves some interaction with the environment. Various essential inputs, such as raw materials and services need to be considered along with all the plant output streams.

Inputs. The principal input for PP is pure propene, with lesser amounts of ethylene for copolymer grades. Energy is required to manufacture these monomers from petroleum feedstocks, and still more is needed for conversion into polymer. At present, most of this power comes from burning fossil fuel which then discharges carbon dioxide and water vapor to the atmosphere. Table 21 compares the overall energy input needed to make various raw materials. This can be expressed either as the weight of oil to produce this energy, or in terms of joules per unit volume. Both values include energy for monomer production, but exclude the hydrocarbon content of the monomer, which is transformed into polymer without combustion. On a weight basis, polyolefin energy requirements are broadly similar to those of most alternative raw materials. On a more realistic volume basis, the strength and lightness of plastics gives energy savings. Usually this is enhanced further in the final article where, for example, thin and strong plastic bottles show savings over their thicker glass counterparts.

Table 21. U.K. energy requirements for the manufacture of natural and synthetic materials [232]

Material	Energy requirements	
	TOE *, overall conversion	kJ/cm^3
Aluminum	5.6	661
Tinplate	1.3	427
Copper billet	1.2	469
Glass bottles	0.5	46
Paper and board	1.4	50
Cellulose film	4.4	293
Low-density polyethylene	1.2	51
PP, old process, with extrusion	1.5	61
PP, new process, with extrusion	1.3	52

* TOE = tonnes of oil equivalent to the energy requirement for overall conversion.

Propene and ethylene monomers themselves are nontoxic asphyxiant gases whose flammable nature calls for the usual extensive precautions. Ignition by static electricity is possible with high-pressure leaks and accidental discharges.

Autoxidation of hot, unstabilised PP powder in storage silos containing air is another known cause of fire.

Effluents. Although catalyst components constitute only a very small proportion of plant materials, both their manufacture and disposal involve noxious substances. Titanium tetrachloride is used for all catalysts, sometimes in considerable excess for high-activity systems. Whereas expensive recycle and recovery stages may be installed as capacities increase, some remaining complexed residues will require disposal. Often, this involves hydrolysis with water to generate corrosive HCl and titanium dioxide suspensions. After neutralization with alkali, these slurries are either discharged as aqueous effluent or settled out and used in landfill. Some incineration is planned. Disposal facilities also need to be capable of receiving occasional faulty catalyst batches. Older plants still using catalyst extraction processes simply use aqueous slurry discharges, or dump concentrated residues from the base of stills.

Lower aluminum alkyls are pyrophoric, react violently with water, and are intensely aggressive towards exposed skin. Safe handling usually calls for full protective clothing. Disposal can be by burning to generate alumina, or quite often, by controlled hydrolysis with water after deactivation with alcohols. Some alkyl manufacturing plants will accept returned waste alkyls for disposal in their own dedicated facilities.

Atactic PP. Older plants needed to dispose up to 5 % of their output as low molecular mass atactic residues from solvent recovery streams. Landfill was a common outlet, with some incineration. Useful low- cost applications appeared in adhesives and roofing felt compositions, which now consume nearly all of the increasingly rare atactic PP byproduct.

Gaseous Effluent. Traditional flare stacks receive most of the voluntary and involuntary process gaseous discharges. Normally, these comprise small flows from distillation column purges which can be dealt with by screened low level flares. These reduce the visual impact of flares which some people find objectionable, especially at night. Some nitrogen purges containing traces of hydrocarbons are discharged to the atmosphere. Scrubbing systems and carbon adsorption beds reduce hydrocarbon emissions, but only a few manufacturers use them because of the cost.

3. Poly(1-Butene)

Hartmut Koch and Ralph L. Mawer

3.1. Production

Introduction. Poly(1-butene) is a thermoplastic polymer produced by solution polymerization of 1-butene with a Ziegler – Natta catalyst system. Hüls developed a process during the 1960s and produced the polymer in a 12 000 t/a plant in the Federal Republic of Germany. Mobil started to develop a process in 1968 and, together with Witco, built a plant in Taft, Louisiana with a capacity of 30 000 t/a. Shell (USA) bought the plant in 1977 and is at present the only commercial producer.

The feedstock of pure 1-butene is supplied from the Shell Higher Olefins Plant in Geismar, Louisiana.

The poly(1-butene) plant produces grades specifically developed for pipe and speciality film applications.

Process. The current commercial poly(1-butene) production process consists of seven primary unit operations: (1) polymerization, (2) deashing, (3) polymer/monomer separation, (4) monomer purification, (5) extrusion, (6) pellet blending, and (7) packaging (Fig. 39).

Figure 39. Flow sheet for the production of poly(1-butene)

a) Monomer purification; b) Polymerization; c) Deashing; d) Monomer/polymer separation; e) Extrusion and pelletizing; f) Blending and storage; g) Packaging

In the polymerization step the catalyst system is fed into the reactor with the purified 1-butene recycle stream. Hydrogen is added as a chain terminator to control the melt flow index of the polymer. Ethylene is fed to the reactor when producing random 1-butene – ethylene copolymers.

Polymerization catalyst residues must be removed from the product to preserve its long-term properties. In the deashing step, the poly (1-butene) is mixed with dilute caustic soda to dissolve and extract the catalyst components. The cleaned hydrocarbon – polymer phase and the catalyst- containing aqueous phase are then separated.

During the polymer/monomer separation step, unreacted 1-butene is separated from the poly(1-butene) for recycle to the reactor. Separation is carried out by heating the polymer solution under pressure then flashing off the monomer by rapidly reducing the pressure. The remaining molten polymer feeds the extrusion step, while the vaporized monomer flows to the monomer purification section of the process.

The monomer purification step accomplishes separation of impurities both heavier and lighter than 1-butene. Water is removed by azeotropic distillation. Fresh 1-butene is added to the process at this stage.

In the extrusion step further volatile hydrocarbons are removed, additives for color, product performance, processing, and stabilization are added, and the polymer is pelletized.

The pellets are pneumatically conveyed to the batch blending stage and then transferred to the packaging area. Pellets are typically sold in 450-kg boxes.

3.2. Properties

3.2.1. *Structure and Physical Properties*

The properties of a high-molecular material are essentially determined by the dimensions and structure of the molecular chain (fine structure) and by the thermomechanical history [233]. Since the fine structure of poly(1-butene) can be varied across a broad range by means of the polymerization process, a knowledge of this is essential for the spectrum of properties.

Molecular Structure. Polymerization with Ziegler – Natta catalysts produces both atactic and isotactic polymer. Atactic poly(1-butene) is virtually impossible to crystallize, while isotactic poly(1-butene) has a crystallinity of 40 – 55 % at normal cooling speeds.

The molecular chains in the crystal form helices. Depending on the crystallization conditions, poly(1-butene) forms 11_3, 3_1 or 10_3 helices, which differ in their helical dimensions [234-236] and give rise to different crystalline modifications (see below).

The isotactic content of poly(1-butene) is generally determined by the solubility in boiling diethyl ether ("ether extract"), whereby it is assumed that only the atactic components are soluble. However, infrared spectroscopy and X-ray crystallography have shown that the atactic extract contains crystallizable components, mostly of low molecular mass. A quicker and more reliable method of determining the atactic content is by evaluating the infrared band in the region of 920 cm^{-1} [237]. This leads to the following definition of the atactic content Y_a:

$$Y_a = \frac{\bar{\nu} - 918\,\mathrm{cm}^{-1}}{30\,\mathrm{cm}^{-1}}$$

where $\bar{\nu}$ is the band position of the unknown sample in cm^{-1}.

The advantage of this method is that it is independent of the molecular mass and of the morphology of the sample.

Molecular Mass. The average molecular mass may be determined either by direct methods such as light scattering or osmometry, or by indirect methods such as determination of the intrinsic viscosity [238], [239]. The molecular mass is calculated from the viscosity number using the Mark – Houwink equation [239]. Mark – Houwink equations for isotactic poly(1-butene), which give virtually identical molecular masses are as follows:

$$[\eta]_{n-\mathrm{nonane}} = 5.9 \times 10^{-5} \times M^{0.80}$$
$$[\eta]_{\mathrm{dekalin},135^\circ\mathrm{C}} = 6.2 \times 10^{-5} \times M^{0.79}$$

These equations also apply to atactic poly(1-butene).

The molecular mass distribution can be determined easily by gel permeation chromatography in 1- chloronaphthalene as solvent. Industrial products have molecular nonuniformities $U = (M_w/M_n) - 1$ between 5 and 12 (M_w = weight-average value, M_n = number-average value).

Crystal Structure and Superstructure. Like most polymers isotactic poly(1-butene) can crystallize in various modifications. However, the polymorphism is more marked and of greater industrial significance in poly(1-butene) than in any other polymer. Four crystal forms of poly(1-butene) are known at present and are designated modification I, I′, II, and III [234], [240]. Characteristic physical data of these modifications are listed in Table 22.

Table 22. Characteristic data for crystal modifications of poly(1-butene)

	Modification II (tetragonal)	Modification I (hexagonal)	Modification III (orthorhombic)	Modification I′ (hexagonal)	Amorphous phase	Reference
Helix type	$11_3/40_{11}$	3_1	10_3	3_1		[235], [240], [242]
Helix length per monomer unit, nm	0.187	0.217		0.217		

Helix cross section, nm^2	0.055	0.044				
Specific volume at 25 °C, cm^3/g	1.1364	1.0453			1.1579	[243]
					1.16 for mod. II	
					1.14 for mod. I	[243]
Specific coefficient of volume expansion, $cm^3\ g^{-1}\ K^{-1}$	3.05×10^{-4}	3.13×10^{-4}			8.12×10^{-4}	[243]
Melting point, °C	ca. 125	ca. 140	93 – 98	100		[241], [244] [245][246]
Heat of fusion, kJ/mol	ca. 3.1	ca. 6.7				[247][248] [249]

Modifications I′ and III are formed on crystallization from solution. They are of no industrial importance. However, modifications II and I, which are obtained by crystallization from the melt, are industrially significant. All the crystal forms can be obtained from modification III in a single step [246], as shown in Figure 40. The transitions from one crystal form to another are monotropic. Modification I′ crystallizes preferentially from solution at lower temperatures [240], while at high temperature the orthorhombic modification III is produced [250], [251]. Modification III is also formed by precipitation, e.g., by addition of methanol to a benzene solution of poly(1-butene) [252]. Modifications I′ and III are also formed in solution or suspension polymerization [253].

Figure 40. Monotropic interconversion of the four modifications of poly(1-butene)

The tetragonal modification II and the hexagonal form I are industrially important. As a melt cools, i.e., after most processing operations, form II crystallizes out first. This is thermodynamically unstable and in the absence of external mechanical stresses it changes monotropically into the stable hexagonal modification I after a period ranging from a few hours to several days, depending on the temperature and thermal history [234]. The transformation from II to I is associated with a change in various physical properties, e.g., an increase in melting point, density, [243] and modulus (Fig. 41).

Figure 41. Time dependence of the shear modulus *G* of modification II of poly(1-butene)

Thermal history: 1 mm thick test bar cooled from the melt (160 °C) in air to the test temperature of 20 °C

These changes in properties are primarily due to the change in crystal modification. The degree of crystallization and the mean spherulite size remain virtually constant during the transition from II to I [243]. The crystallite size also remains unchanged [244]. This is a purely crystal – crystal transformation without experimentally detectable melting of modification II crystals.

The rate of conversion, as indicated for example by the half-value time $t_{1/2}$ depends on the thermal history (Fig. 42) and on the temperature (Fig. 42).

Figure 42. Time dependence of specific volume during transformation (II $\longrightarrow$ I) of poly(1-butene) at 20 °C

a) Quenched; b) Crystallized for 200 min at 92 °C; c) Crystallized for 5700 min at 102 °C; d) Crystallized for 5600 min at 102 °C; e) Crystallized for 7500 min at 106 °C; f) Crystallized for 7200 min at 108 °C

Figure 43. Temperature dependence of half-value time $t_{1/2}$ for the transition II $\longrightarrow$ I

a) Pure poly(1-butene); b) Melt mixture of poly(1-butene) and polypropylene in the ratio of 1: 1; c) Poly(1-butene) with 30 % butyl stearate

Mechanical stresses may significantly increase the conversion rate [254], [255]. Figure 44 shows the influence of constant tensile stress on the conversion rate, monitored by IR spectroscopy. Whereas these measurements show a stress-free sample to have a half-value time of 5500 min, the half value for a sample under a tensile load of 4.4 MPa is only ca. 10 min. Internal stresses and orientations have a similar effect to external stresses. The conversion of II to I is also accelerated by hydrostatic pressure [256]. The conversion rate can also be increased by certain additives, such as polypropylene or plasticizers (see Fig. 43) [240], [257], [258].

Figure 44. Poly(1-butene) conversion curves for modification II $\longrightarrow$ I for various constant tensile stresses

R is the ratio of the IR extinction of modification I at 920 cm^{-1} to the extinction of modification II at 920 cm^{-1}. The half-value time $t_{1/2}$ (II $\longrightarrow$ I) is reached when *R* has a value of ca. 1.5

a) 0 MPa; b) 0.12 MPa; c) 1.48 MPa; d) 1.91 MPa; e) 2.55 MPa; f) 2.95 MPa; g) 4.23 MPa

The molecular mass and the molecular mass distribution have virtually no effect on the conversion rate. However, the molecular mass does have significant influence on the rate of crystallization of modification II (Fig. 45). The crystallite and spherulite sizes of all crystal modifications can be varied over a broad range by modifying the cooling and crystallization conditions of the melt [248], [259], [260]. Surprisingly, the mean crystallite size and size distribution are not increased by subsequent tempering [259], [260]. This may be a reason for the low time dependence of certain mechanical properties (see Mechanical Properties.).

Figure 45. Crystallization time t_c of poly(1-butene) at 78 °C as a function of the viscosity-average molecular mass $\bar{M}_v$

Curve: measurements on fractions, ▪ unfractionated product

The four modifications are distinguished analytically and characterized quantitatively by a combination of X-ray, infrared, and differential thermal analysis [245-247], [261].

3.2.2. *Application Properties*

In normal processing operations, isotactic poly(1-butene) is heated to above its melting point. Therefore it is the unstable modification II which forms immediately after cooling, and is converted to the stable form I during storage or on application of mechanical stress. Since only the properties of form I are of interest from the point of view of applications, the statements below refer only to this modification.

In terms of density, melting point, and glass transition temperature, poly(1-butene) resembles polyethylene rather than polypropylene [262]. This similarity extends to cross-linked polyethylenes, although some of their properties naturally vary, depending on their cross-linking density [263]. Commercial material is around 40 % to 55 % crystalline. Since the crystallization rate is slow by comparison with polyethylene and polypropylene, superstructures which are of interest for applications can be obtained by the choice of cooling conditions [264]. Nucleators increase the rate of crystallization, leading in some conditions to a material that is somewhat more brittle at low temperature [264].

Mechanical Properties. Table 23 lists some mechanical properties of poly(1-butene), polyethylene, and polypropylene. According to the VDE hardness, poly(1-butene) is softer than polyethylene and polypropylene. However, the Shore hardness is virtually the same as for polyethylene. The surface gloss of components made from poly(1-butene) is similar to those made from polypropylene [265].

Table 23. Hardness, rigidity and strength of low-pressure polyolefins [265]

Property	Test method	Polyethylene	Polypropylene	Poly(1-butene)
VDE hardness (60 s), MPa	VDE 0302	44 – 64	61 – 80	25 – 45
Shore D hardness	DIN 53 505	62 – 69	70 – 75	60 – 68
Flexural stress at conventional deflection, MPa	DIN 53 542	26 – 43	34 – 50	15 – 25
Modulus of elasticity, MPa	[a]	900 – 1200	1000 – 1500	500 – 900
Impact strength	DIN 53 453	no break	no break	no break
Notched impact strength, kJ/m^2	DIN 53 453	5 to no break	3 – 15	20 to no break
Brittle point, °C	ASTM D 746–57T	below – 70	+ 20 to – 5	– 10 to – 30

[a] Measured in Hooke range by bending tests.

The rigidity of poly(1-butene) is relatively low. The flexural stress at conventional deflection and modulus of elasticity are lower than for polyethylene (Table 23).

The impact strength and notched impact strength are significantly higher than those of polypropylene. Above 0 °C the values are similar to those for high molecular mass polyethylene, but at lower temperature they are inferior [265]. Nevertheless the low-temperature strength, as characterized by the brittle point, is relatively good [254], [265].

The stress – strain behavior of modification I differs noticeably from that of other polyolefins. The differences are not only in the shape of the stress – strain curve, which for industrial material has virtually no maximum [265], [266], but also in the dependence on time and temperature [267]. Figure 46 shows the yield strength σ_{ys}, measured in an uniaxial tensile test as a function of the stretching time t_s. Whereas the yield strength of polyethylene and polypropylene declines sharply with increasing stretching time, the values for poly(1-butene) remain virtually constant above 0.1 s. The good creep resistance and resistance to stress cracking of poly (1-butene) pipes subject to internal pressure [262] is due to the low time dependence of the mechanical properties.

Figure 46. Yield strength σ_{ys}, measured in a tensile test at 22 °C, as a function of the stretching time t_s [266]

a) Polyethylene; b) Polypropylene; c) Poly(1-butene)

Since this low time dependence of the mechanical characteristics is maintained at higher temperatures, poly(1-butene) is particularly suitable for hot-water pressure pipes [263], [268]. Figure 47 shows the burst hoop stress performance of poly(1-butene) pipe under internal pressure according to ISO-SEM (DIS 9080) [269].

Figure 47. Burst hoop stress performance of poly(1-butene) pipes

As well as the outstanding resistance to stress cracking, the unusually good creep behavior is significant. The tendency to creep, i.e., to undergo plastic deformation below the yield point, is significantly lower than for other polyolefins, even at temperatures up to 100 °C [263], [265], [270]. This is also an essential requirement for the use of poly (1-butene) as a film material, particularly for the packaging sector [270].

Electrical Properties. The electrical behavior of poly(1-butene) does not differ significantly from that of polyethylene and polypropylene [265]. Apart from the usual quantities of stabilizers, it only contains residues of polymerization catalysts. Because of its good resistance to chemicals, outstanding resistance to stress cracking, and flexibility, poly(1-butene) is an important material for special applications in the cable and electrical industry.

Resistance to Chemicals and Gas Permeability. Because of its paraffinic structure, poly(1-butene) is resistant to most common chemicals such as acids, alkalies, salts, alcohols, and ketones. However, it swells or dissolves in hot aromatic and chlorinated hydrocarbons. It is less inert to aliphatic hydrocarbons than polyethylene and polypropylene and more prone to permeation [265], [271], [272]. A detailed table on the resistance of poly(1-butene) to chemicals is given in [270].

Permeability to gases and vapors, in particular water and oxygen, is comparable to that of polyethylene of similar crystallinity. Permeability to carbon dioxide, however, is higher [264].

3.3. Processing

Processing poly(1-butene) on conventional machines presents no problems. Because of its low crystallite melting point and particularly because of the rapid decrease in melt viscosity with increasing temperature, poly(1-butene) can be processed by extrusion (pipes, profiles, sheets), extrusion blow molding (hollow bodies), and injection molding (engineering products, sheathing for metals) [265]. Sheets made by extrusion or compression molding can be shaped hot or cold. A special feature is cold shaping of the relatively soft modification II. Articles shaped from this modification then become increasingly rigid as the conversion to modification I progresses.

3.4. Applications

Pipe. The major outlet for poly(1-butene) is currently in high-performance pipes, which exploit its creep resistance and long lifetime at elevated service temperatures, flexibility, light weight, corrosion resistance, and its ability to be heat welded [263]. It competes in plumbing and radiator heating applications with copper, where progress is mainly limited by resistance to replacing traditional working practises. In the underfloor heating pipe market it competes with other plastics such as cross-linked polyethylene and polypropylene.

The advantage of poly(1-butene) over other polymers in both these applications is its better ability to retain its mechanical and performance properties at elevated temperature. For instance a comparison of tangent modulus, yield stress, ultimate stress, and elongation at break within and transverse to the extrusion direction of the pipes shows a more balanced performance for pipes made of poly(1-butene) [273]. In the last decade the long-term properties of poly(1-butene) pipes and their lifetime at temperatures up to 120 °C have been studied [274] and the methodology for such long-term tests has been developed for various plastics [275-277].

Extrapolation methods give estimated lifetimes of 50 years at 70 °C [273]. A recent evalua-tion of pipes based on polymers as well as traditional materials, such as copper, favored poly(1-butene) [278].

The problem of oxygen diffusion in plastic piping systems, which was given as one explanation of corrosion in metal radiators, tanks, and boilers in the past, has been resolved by the use of multilayer pipes containing an oxygen-barrier layer and the addition of inhibitors to the circulating hot water [278].

Packaging. In the packaging sector, poly (1-butene) has become established in speciality film applications which require resistance to cooking temperatures, and in heat-seal layers for oriented polypropylene, which exploit the high compatibility of poly(1-butene) with polypropylene. The incompatibility of poly(1-butene) in blends with various polyethylenes and ethylene copolymers, such as low-density polyethylene, linear low-density polyethylene, high-density polyethylene and ethylene – vinyl acetate copolymers, forms the basis of peelable seals (see Fig. 48).

Figure 48. Cross section of a coextruded peel-seal layer on an LDPE substrate

a) LDPE substrate; b) Peel-seal blend LDPE in which incompatible poly(1-butene) particles are dispersed

Peel-seal technology provides a robust pack, yet allows the consumer to open it easily without ripping or tearing. The key attributes of systems based on poly(1-butene) are the broad heat sealing range and the cohesive failure mechanism, which results in an aesthetically attractive package after opening. This is because cohesive failure propagates through the peel-seal layer itself due to the weaker intermolecular forces between the dissimilar materials, and results in clean uniform separation. Additional advantages are good clarity and a clean peel with no stringing [279], [280]. The more conventional system relies on delamination between layers as a result of adhesive failure and is also more difficult to control.

A correlation of peel-seal strength with blend composition and temperature is shown in Figure 49.

Figure 49. Dependence of peal-seal strength on blend composition

Manufacture of packaging film or sheet incorporating a poly(1-butene) peel-seal blend is possible by all the conventional processes such as film blowing or casting, sheet extrusion or coextrusion, extrusion or coextrusion coating, and lamination.

Poly(1-butene) peel seals are used in flexible packaging such as box liners for cereals, cake mixtures, and biscuits. In combination with more sophisticated barrier films, they are used for processed meat and vegetable packs. They are also used for packaging medical products.

An important growth area for peelable seals is in lids for rigid or semirigid containers. These range from the relatively simple yogurt, milk, and cream pots to individual-portion containers for microwave meals.

Two features of poly(1-butene) peel seals are considered to be of particular importance to the development of the next generation of high-performance packages. The first is their resistance to high-temperature cooking or sterilization. Often referred to as “retortability”, this is an increasingly important feature both in the food and nonfood sectors. Poly(1-butene) peel seals can be made heat resistant by formulation with higher-temperature-resistant materials such as polypropylene or high-density polyethylene.

The second important feature is a distinct whitening effect when the seals are opened because of the characteristic cohesive failure mechanism. This gives a clear indication that the package has been opened or tampered with.

4. Polyisobutylene

Wolfgang Immel

4.1. Introduction

Industrially important polyisobutylenes can be divided into five groups:

1. Di-, tri-, and tetraisobutenes
2. Low molecular mass polyisobutylenes with $\bar{M}_n$ = 330 – 1600
3. Medium molecular mass polyisobutylenes with $\bar{M}_n$ = 20 000 – 45 000
4. High molecular mass polyisobutylenes with $\bar{M}_n$ = 75 000 – 600 000
5. Ultra high molecular mass polyisobutylenes with $\bar{M}_n$ > 760 000

History. In 1925 LEBEDEW was the first to prepare polyisobutylene [281], [282]. He obtained products of varying chain length: liquids of oily to honey-like consistency; sticky, doughy materials; or solid, rubber-like materials.

Relatively uniform low molecular mass polyisobutylenes were first obtained by the company de Bataafse [283] by polymerizing isobutene at + 10 to – 10 °C in the presence of metal halides.

High molecular mass polyisobutylenes were first prepared by OTTO and MÜLLER-CUNRADI by polymerizing isobutene below – 10 °C in presence of volatile inorganic halides [284].

Polymerization Mechanism. Even in the early studies, two important aspects of the polymerization of isobutene were recognized: (1) catalysis with initiators of the Friedel – Crafts type, and (2) the inverse dependence of the molecular mass on the temperature. Subsequent studies led to the first formulations of a reaction mechanism [285].

According to these ideas, which essentially remain valid today, the reaction consists of the following steps:

Initiation:

$$BF_3 + HX \longrightarrow H[BF_3X]$$

$$H[BF_3X] + \begin{array}{c} CH_3 \\ | \\ C{=}CH_2 \\ | \\ CH_3 \end{array} \longrightarrow \left[CH_3{-}\begin{array}{c} CH_3 \\ | \\ C \\ | \\ CH_3 \end{array} \right]^+ [BF_3X]^-$$

Chain growth:

$$\left[CH_3{-}\begin{array}{c} CH_3 \\ | \\ C \\ | \\ CH_3 \end{array} \right]^+ + n\, CH_2{=}\begin{array}{c} CH_3 \\ | \\ C \\ | \\ CH_3 \end{array}$$

Chain termination:

The initiator is a Lewis acid (BF_3, $AlCl_3$) in combination with a proton source, which is usually present as a trace impurity, e.g., water, hydrogen, fluoride, or hydrogen chloride.

The competition between the growth reaction and chain termination determines the chain length (i.e., the molecular mass). Since the activation energy of chain termination is higher, increasing the polymerization temperature lowers the polymer chain length (ln M ~1/T).

Meanwhile [286], a series of studies have appeared which have revealed a considerably refined view of the course of the reaction; yet a comprehensive mechanism which is consistent with all experimental findings is still lacking. Other studies deal with new initiators (aluminum alkyls; inorganic initiators such as acid clays and molecular sieves; Ziegler catalysts; high-energy radiation as an initiator). However, none of these new catalyst systems are used industrially. Industrial processes for polyisobutylene production still use the conventional Friedel – Crafts catalysts, boron trifluoride and aluminum chloride.

4.2. Production

4.2.1. *Isobutene as Raw Material*

The production of isobutene is described in ⟶ Butenes – Resources and Raw Materials, ⟶ Butenes – Upgrading of Butenes.

The purity requirements for the isobutene differ according to the type of polyisobutylene produced.

For the production of low molecular mass polyisobutylenes, butadiene-free C_4 fractions can be used, which apart from isobutene contain *n*-butane, isobutane, and *n*-butenes; stricter requirements are set for the isobutene for high molecular mass and solid polyisobutylenes.

During isolation of isobutene from C_4 fractions, an isobutene must be obtained which is as free from *n*-butene as possible. Primarily the content of *cis*- and *trans*-2-butene must be minimized. Both are powerful polymerization poisons and chain terminators. On the other hand, 1-butene can be used as a regulator in the production of high molecular mass and solid polyisobutylenes.

4.2.2. *Low Molecular Mass Polyisobutylenes*

Figure 50 shows the layout of the Cosden Petroleum continuous process, which can be regarded as a kind of fluidized-bed process.

Figure 50. Cosden Petroleum process for producing low molecular mass polyisobutylene

a) Preliminary distillation; b) Absorption column; c) Caustic soda solution wash tower; d) Heat exchanger; e) Water separator; f) Silica gel towers; g) Heat exchanger; h) Reaction vessel; i) Mixing tank; j) Refrigeration unit; k) Gear pump; l) Pump; m) Offtake pipe; n) Cooler; o) Stripping column; p) Clay-filled tower; q) Distillation column; r) Water cooler; s) Pressure column; (For A to D, see text)

A liquefied refinery-gas mixture with C_1 – C_5 hydrocarbons and an isobutene content of 3 – 50 % is freed from pentenes in a preliminary distillation, enriched in isobutene in an absorption column, washed in a wash tower with ca. 20 % caustic soda solution to remove sulfur, cooled in a heat exchanger, dewatered in a water separator, dried in silica gel towers and, after further low-temperature cooling in a second heat exchanger, introduced into the lower part of the reaction vessel. The polymerization takes place here at temperatures between – 43 and +16 °C and pressures of 0.1 – 0.35 MPa, so that the liquid phase is maintained. The catalyst used is a mushy suspension of finely divided (50 – 100 mesh) aluminum chloride in dry, liquid polyisobutylene, which is prepared in a mixing tank and supplied to the reaction vessel by a gear pump.

The quantity of aluminum chloride is about 10 – 20 % of the total hydrocarbons in the reaction mixture. The activity of the aluminum chloride is increased by adding 0.08 – 0.12 % hydrogen chloride (relative to aluminum chloride) as activator and accelerator. Water or chloroform have the same effect. The diameter of the reaction zone (A) and the feed rate of the catalyst slurry are so matched to each other that the aluminum chloride particles do not settle. Zone (B) of the reaction vessel, with a diameter two to six times that of zone (A), reduces the flow rate by a factor of about three to four, and functions as a calming zone. It merges into the settling zone (C), in which the aluminum chloride particles settle and are pumped off as a suspension through the offtake pipe which extends into zone (B). This catalyst slurry returns via a cooler into the reaction zone (A). Spent, aggregated catalyst is discharged at the bottom of the reaction zone.

A variant of the process uses separate vessels for polymerization and for catalyst settling.

From the settling zone flows a clear, light solution of liquid polyisobutylene in unreacted starting material. To improve the yield, the reaction mixture is pumped at least four times, but usually more than eight times, through the reaction zone (A). The clear polymer solution flows through the heat exchangers (g) and (d) to cool the isobutene and, after a water wash to remove acidic constituents, into a stripping column in which about one to two thirds of the inert, unreacted starting material is distilled off. After post-treatment of the concentrated polymer solution in a clay-filled tower, which may precede the stripping column, all volatile constituents of the starting material, especially unpolymerized isobutene, are vaporized in a distillation column and returned via a water cooler into the absorption column. In a further column, the last traces of volatile constituents are distilled from the liquid polyisobutylene at atmospheric pressure.

Aside from this process of the Cosden Petroleum Corp., others have been developed. For a description of the BASF and Exxon processes, see [287, pp. 94 – 97], [288].

4.2.3. *Medium Molecular Mass Polyisobutylenes*

The basic principle of the Exxon process for producing medium molecular mass polyisobutylenes (Fig. 51) [289] resembles the process for low molecular mass polyisobutylenes. However, a purer isobutene is used as starting material and pentane or hexane is added as solvent. The polymerization temperature must be lower to obtain a higher molecular mass. A mixture prepared from fresh isobutene, recycled isobutene, and hexane with 30 % isobutene and 70 % hexane is brought via a heat exchanger and a cooler to the polymerization temperature of – 40 °C and fed into the reaction vessel. Simultaneously, a slurry of 5 % finely divided aluminum chloride in hexane at a temperature of below – 23 °C flows into the reaction vessel.

Figure 51. Exxon process for producing medium molecular mass polyisobutylenes

a) Mixing vessel; b) Reaction vessel; c) Heat exchanger; d) Nozzle mixer; e) Cooler; f) Settling tank; g) Degasser; h) Degassing vessel; i) Water separator

The polymerization takes place with powerful stirring so that the aluminum chloride does not settle, and external cooling. The throughput is 378.5 L/h isobutene – hexane mixture and 0.454 kg/h $AlCl_3$. The resulting solution of polyisobutylene in hexane with suspended aluminum chloride is drawn off, and after it has passed through a heat exchanger an excess of dilute caustic soda solution is added to destroy the catalyst. After thorough mixing in a nozzle mixer, the mixture of polymer solution and dilute caustic soda solution runs into a settling tank, where it forms two layers. The lower layer, consisting of dilute caustic soda solution, aluminum hydroxide, and salts, is discarded. The upper layer, consisting of a solution of polymer in hexane and unreacted starting material, is fed into a degassing vessel, in which the lower boiling

components, principally unreacted isobutene, are stripped off at 99 °C and 0.35 bar. *n*-Butenes if present are removed from the system to avoid poisoning the reaction. In a second degasser, the last traces of volatile constituents are removed. The unreacted isobutene is condensed, dewatered in a water separator, and added as recycle isobutene to the starting mixture.

In its batch process for producing medium molecular mass polyisobutylenes, BASF makes use of the chain-terminating effect of diisobutene [287, pp. 88 – 91], [290].

In a conical reaction vessel with good thermal insulation, pure, dry liquid isobutene and pure, dry liquid ethylene as internal coolant are mixed in the ratio 1 : 2. The quantity of diisobutene added to the isobutene depends on the desired molecular mass of the polyisobutylene. A sufficient quantity of gaseous boron trifluoride for the polymerization is then carefully introduced into the mixture. The mixture starts to boil, and the evaporating ethylene removes the heat of polymerization. The polyisobutylene remains behind in the reaction vessel in the form of a white foam. It is removed from the vessel and freed from all volatile constituents in a degassing machine.

4.2.4. *High Molecular Mass Polyisbutylenes*

BASF and Exxon have developed continuous processes for producing high molecular mass solid polyisobutylenes [287, pp. 97 – 104].

BASF Belt Process. In the belt process, the conical polymerization vessel of the BASF batch process described above is replaced by a continuous polymerization belt (Fig. 52) [291].

Figure 52. BASF belt process for high molecular mass polyisobutylenes

a) Steel belt; b) Twin-screw machine; c) Cooling and compounding; d) Purification

A gently inclined trough-shaped continuous steel belt, 16 – 18 m long and 50 cm wide, runs in a gastight housing over a drive roller and a tension roller. A mixture of pure, dry liquid ethylene and isobutene in the ratio 1 : 1 flows through a pipe onto one end of the steel belt. From a second pipe a solution of boron trifluoride in the same quantity of ethylene as is mixed with the isobutene is added. The quantities of cocatalyst and chain-length regulator [287, pp. 82 – 91]depend on the desired molecular mass. The polymerization starts instantly. It continues at the boiling point of the liquid ethylene (–103.7 °C) and in a short time is ended. The heat of polymerization is absorbed by the evaporation of ethylene. The vaporized ethylene is recycled via a purification and liquefaction system. The polyisobutylene is stripped from the steel belt with a scraper and degassed and homogenized in a twin-screw machine.

Exxon Process. Polyisobutylene is also produced by the process used for butyl rubber (see ⟶ Rubber, 3. Synthetic) [292].

4.3. Structure

The polymer obtained by cationic polymerization has the following structure:

In the stretched state polyisobutylene gives a well-developed X-ray diffraction pattern which shows that 8 monomers with their 16 methyl groups are arranged in an almost regular helix around the principal axis, forming one translation period of the chain after 3 rotations [293].

It has been shown by IR spectroscopy that the principal end group is the methylene group [294].

4.4. Properties

The rubber-like polyisobutylenes, like all other polyisobutylenes, owe their physical and chemical properties to their paraffinic character. This results in a low glass transition temperature, low specific thermal conductivity, very low water vapor permeability, high dielectric strength, high resistivity, low dielectric constant, low dielectric loss factor, high ageing resistance, and rot resistance as well as an unusually wide-ranging chemical resistance. The good solubility in hydrocarbons and chlorohydrocarbons and the insolubility in alcohols, esters, and ketones also result from the paraffinic nature of the polyisobutylenes.

At room temperature, polyisobutylenes are resistant to dilute and concentrated hydrochloric acid, sulfuric acid, phosphoric acid, chlorosulfonic acid, phenolsulfonic acid, naphthalenesulfonic acid, formic acid, acetic acid, ammonia, potassium hydroxide solution, caustic soda solution, as well as aqueous calcium hydroxide, aqueous hydrogensulfite, copper sulfate solution, potassium permanganate solution, hydrogen peroxide, chromic acid, and dichromate solution. Above 80 °C, concentrated sulfuric acid causes carbonization and concentrated nitric acid causes decomposition.

Some properties of polyisobutylene that are independent of the degree of polymerization are as follows:

Density, g/cm^3	0.92
Volume coefficient of thermal expansion at 20 °C, K^{-1}	6.3×10^{-4}
Specific heat, kJ kg^{-1} K^{-1}	2.0
Glass transition temperature (DSC), °C	– 60
Thermal conductivity, W K^{-1} m^{-1}	0.19
Refractive index n_{20}^{D}	1.51
Dielectric constant ϵ_r (50 Hz, 20 °C) DIN 53 483	2.2
Dielectric loss factor tan δ (50 Hz, 20 °C) DIN 53 483	$\leq 5\times10^{-4}$
Water vapor permeability, g m^{-1} h^{-1} mbar^{-1}	2.5×10^{-7}

Further properties are listed in Tables 24 and 25.

Table 24. Properties of polyisobutylenes dependent on degree of polymerization, exemplified by Oppanol B (BASF)

Oppanol	Viscosity, Pa · s		Intrinsic viscosity	Number-average molecular

4.5. Uses and Processing

The low molecular mass polyisobutylenes are used as plasticizing components for modifying sealants. In addition, they are used for producing insulating oils.

After further functionalization with polar groups, the low molecular mass polyisobutylenes are used as dispersants in fuel and lubricant additives.

The medium molecular mass polyisobutylenes are chiefly used as raw materials for adhesives and sealants. Due to their very low water-vapor permeability, permanently flexible sealants based on polyisobutylene – carbon black are important in the production of sealed double glazing units. Combinations of polyisobutylene with paraffin or wax are used for impregnating paper and board.

The breaking point of bitumen is lowered and its flexibility improved by addition of medium molecular mass polyisobutylene.

High molecular mass polyisobutylenes are used as blends with medium molecular mass grades for producing self-adhesive compounds, e.g., for adhesive plasters.

Because of their good tolerance by the skin, filled polyisobutylenes are used to produce sealing rings for colostomy bags.

Unstabilized polyisobutylenes are used in chewing gum bases.

Blending polyisobutylenes with paraffin oil and inorganic fillers gives permanently elastic sealants, which are usually marketed in extruded form as strip or round-profile string.

High molecular mass polyisobutylenes with high filler contents are used to produce sheets that are used for sealing buildings against groundwater and seeping water as well as for protection against corrosion and radiation. Conductive and magnetic polyisobutylene sheetings are also available.

The cold impact resistance of polypropylene is improved by blending with polyisobutylene. The sensitivity of polyethylene to environmental stress cracking is reduced by adding polyisobutylene.

Polyisobutylenes are compatible with natural and synthetic rubber and with reclaimed rubber.

Solutions of ultra high molecular mass polyisobutylenes ($\overline{M}_n$ > 760 000) in organic solvents even in low concentrations (<< 1 %), have pronounced viscoelastic properties and distinctly increased extensional viscosity.

Polyisobutylene can be compounded on a roll mill or in an internal mixer. Compounding is carried out at 140 – 170 °C to minimize thermal degradation of the polyisobutylene.

4.6. Commercial Products

BASF, Germany:	Oppanol B 3 (liquid); Oppanol B 10, B 12, B 15 (flexible resin-like, tacky); Oppanol B 50, B 80, B 100, B 120, B 150, B 200, B 246 (solid, rubber-like)
Exxon, United States:	Vistanex LM-MS, LM-MH (flexible resin-like, tacky); Vistanex MM L-80, MM L-100, MM L-120, MM L-140 (solid, rubber-like)

In addition, a range of low molecular mass polyisobutylenes are marketed.

4.7. Copolymers [295]

Isobutene – isoprene – divinylbenzene terpolymers are produced under conditions similar to those used for butyl rubber, with the addition of divinylbenzene. Unlike butyl rubber, they exhibit no cold flow.

Isobutene – styrene copolymers behave similarly to polyisobutylenes or butyl rubber.

The copolymers have no economic significance.

[Top of Page]

5. Poly(4-Methyl-1-Pentene)

T. Geoffrey Heggs

As described for polypropylene in Chapter Polypropylene, Ziegler – Natta stereospecific catalysts discovered in 1954/1955 polymerize α-olefins to crystalline products. Foremost of these are polypropylene and, to a lesser extent, poly(1-butene), but higher α-olefins also yield crystalline products having helical chains in the crystallites [296-298]. Much laboratory work on C_5 – C_{18} olefins centers on polymerization mechanisms and the interesting crystallization behavior of homopolymers and copolymers, but only poly(4-methyl-1-pentene), PMP, based resins have reached commercial production status. Their excellent optical clarity combined with a high melting point, reasonable toughness, and general inertness has led to use in demanding applications where the much higher raw material cost is a secondary consideration. Operating temperatures for PMP in service can be as high as 200 °C for short times, after which thermal oxidation is likely to start. For this reason and because of impact strength limitations, the potential advan-tages of even higher melting poly(α-olefins) cannot be realized in practice. Engineering resins such as polyimides, polysulfones, and polysulfides must be used for sustained high-temperature operations and extra toughness.

4-Methyl-1-pentene monomer can be polymerized with cationic and Ziegler – Natta catalysts. The former cause some isomerization and yield irregular chains, giving amorphous viscous liquids or rubber-like solid products of little commercial interest [299], [300].

In 1965 ICI made several grades of PMP, under the trade name TPX, in its semitechnical plant at Welwyn Garden City for distribution and in-depth evaluation [301]. Manufacture on its Wilton production site started in June 1968 on a 2000 t/a plant producing transparent and opaque grades. In 1973 the process was sold to Mitsui Petrochemical Industries, which became the sole manufacturer on its plant at Iwakuni-Ohtake works in Japan. Capacity was increased from 2000 t/a to 3000 t/a in 1982, and then to 6000 t/a in 1983. In 1989, Phillips 66 in Bartlesville, United States, started supplying development quantities from a 250 t/a pilot plant in the United States under the trade name Crystalor.

5.1. Raw Materials

5.1.1. *Monomers*

Several monomers are used in TPX production to overcome the deficiencies of haze and brittleness in pure homopolymers of 4-methyl-1-pentene. The restricted availability of these monomers in commercial quantities in the early 1960s proved troublesome for ICI's development program.

Polar and highly unsaturated contaminants retard polymerizations with Ziegler – Natta catalysts. Handling precautions must recognize flammability hazards and facile peroxidation of these liquid monomers on exposure to air. At high concentrations they exert a narcotic effect.

4-Methyl-1-pentene (4MP) is prepared by selectively dimerizing propene at ca. 150 °C and 10 MPa with supported alkali metals, particularly potassium. British Petroleum first established a commercial process in 1967, followed by further patents to Chevron and Idemitsu (Table 26). All these processes yield a liquid fraction containing ca. 80 % of 4MP. Separation of pure 4MP from the C_6 fraction requires superfractionation with a 100-plate column.

Table 26. Dimerization of propene to 4-methyl-1-pentene [298]

Company	Process	Catalyst	Temperature, °C	Pressure, MPa	Yield *, % 4MP	Patent priority
British Petroleum [302]	rocking bed	K on graphite	160	11	85	12.12.62
British Petroleum [303]	fixed bed	Na on K_2CO_3	160	12	75	8.8.63
Chevron [304]	slurry	K on $MgSiO_3$	150	5	80	17.5.66
Idemitsu [305]	slurry	K/Cu/*tert*-amine	180	7	90	13.4.76

* In liquid fraction.

Apart from being the main feedstock for PMP manufacture, 4MP is now used as comonomer in certain grades of linear low-density polyethylene. However, 4MP is not traded commercially, and there is no quoted price. The current name plate capacity of Mitsui Petrochemical Industries plant for 4MP is 13 000 t/a.

A typical analysis (wt %) of 4MP monomer used by ICI to make TPX is as follows:

4-Methyl-1-pentene	97.4
Lighter than C_6	0.1
cis-4-Methyl-2-pentene	0.9
trans-4-Methyl-2-pentene	1.5
1-Hexene	0.1

Some physical properties of 4MP [306], [307], relevant to its polymerization are:

bp, °C	53.86
mp, °C	– 153.64
Density at 20 °C, g/cm^3	0.6637
Vapor pressure at 20 °C, kPa	29.47
Vapor pressure at 50 °C, kPa	89.34
Refractive index n_{20}^{D}	1.38267
Heat capacity of liquid at 25 °C, J g^{-1} K^{-1}	2.191
Heat of vaporization at *bp*, J/g	0.3221
Flash point, °C	– 7.0
Autoignition temperature, °C	300

Linear C_6 – C_{12} α-Olefins. Most commercial grades of PMP contain small amounts of higher α-olefins as comonomer to modify the main chain. Usually, the even carbon

number olefins are made by oligomerizing ethylene with triethylaluminum or soluble nickel complexes. Commercial quantities of these pure olefins up to C_{18} are priced at about £1/kg. Table 27 lists some of their physical properties, together with those of useful branched comonomers.

Table 27. Physical properties of some comonomers * [306]

Comonomer	*bp*, °C	*mp*, °C	Density at 20 °C, g/cm^3	*mp* of isotactic homopolymer, °C
1-Pentene	29.96	– 165.22	0.6405	75 – 80
3-Methyl-1-butene	20.05	– 168.49	0.6272	310
1-Hexene	63.48	– 139.83	0.6732	amorphous at 20 °C
3-Methyl-1-pentene	54.17	– 153.0	0.6674	> 350
4-Methyl-1-pentene	53.86	– 153.64	0.6637	235 – 250
4,4-Dimethyl-1-pentene	72		0.6827	> 380
1-Octene	121.29	– 101.72	0.7149	34
1-Decene	170.60	– 66.28	0.7408	45
1-Dodecene	213.30	– 33.60	0.7583	60

* Data for 4-methyl-1-pentene included for comparison.

5.1.2. *High-Melting Nucleating Polymers*

It is reported [308], [309] that < 1 % of well dispersed high-melting polymers from branched α-olefins nucleate PMP crystallization to enhance transparency. Isotactic polymers of 3-methyl-1-butene, 3-methyl-1-pentene, and 4,4-dimethyl-1-pentene are preferred. These branched monomers are much more expensive than linear α-olefins because they arise only as minor byproducts from refining and cracking operations, or by special synthesis. For example, 3-methyl-1-butene can be prepared by dehydrating isoamyl alcohol. The same isospecific catalysts used to polymerize 4MP are also suitable for making these branched olefin polymers (see Section Industrial Manufacture). Preferably these high-melting polymers are prepared as a stage of the PMP polymerization process, rather than as separate additives.

5.1.3. *Catalysts*

Most Ziegler – Natta catalysts suitable for polypropylene polymerize and copolymerize 4MP to give linear head-to-tail polymers. The reactivity of the higher α-olefins is appreciably lower than that of propene under comparable conditions. Copolymerization data compiled by KISSIN [310], [311] illustrate how branching and chain length impede reaction with titanium-based catalysts (Table 28). Steric hindrance by bulky groups in the 3-position, adjacent to the double bond, is particularly pronounced (3-methyl-1-butene and 3-methyl-1-pentene). 4-Methyl-1-pentene is several times less active than propene, as are all the higher linear α-olefins. Low overall reaction rates arise when some of the active sites on certain catalysts are inaccessible to bulky monomers [311].

Table 28. Relative copolymerization activities r_2 of higher α-olefins relative to propene [310]

Monomer	r_2 *
Ethylene	8 – 20
Propene	1
1-Pentene	0.2 – 0.5
1-Hexene	0.2 – 0.4
1-Decene	0.1 – 0.3
1-Octadecene	0.1 – 0.15
3-Methyl-1-butene	0.02 – 0.06
3-Methyl-1-pentene	0.05
4-Methyl-1-pentene	0.15

* Ratio of propagation rates, $r_2 = k_2^2 / k_2^2$.

It is necessary to use highly isospecific catalysts to achieve good yields of crystalline polymer without much atactic byproduct. Preferred systems use combinations of $TiCl_3$ with $Al(C_2H_5)_2Cl$ as activator [312], or possibly the newer supported catalyst systems such as $TiCl_4$ – $MgCl_2$ – $Al(C_2H_5)_3$ with an appropriate Lewis base [313]. Catalysts made directly from $TiCl_4$ and organoaluminum compounds only yield 60 % of crystalline polymer, and even violet $TiCl_3$ activated with aluminum trialkyls produces some 20 % of solubles. These trialkylaluminum – titanium halide systems also cause some isomerization of 4MP, but this is completely avoided with $TiCl_3$ – $AlEt_2Cl$. The original ICI process used a coarse, preformed spherical $TiCl_3$ made by controlled reduction of $TiCl_4$ with alkyl aluminum chlorides. Experiments showed that it was important to secure a very mobile slurry to permit thorough catalyst extraction for the highest polymer transparency.

5.2. Industrial Manufacture

Published information on the production of TPX is very limited apart from the disclosures of ICI. Details which follow relate to their early slurry process, but some improvements have been introduced by Mitsui Petrochemical Industries as their manufacturing capacity expanded from 2000 to 6000 t/a.

Semibatch polymerizations used a conventional water-jacketed stirred reactor containing inert aliphatic hydrocarbon diluent, $AlEt_2Cl$, and particle-form purple $TiCl_3$ catalyst. A nucleating polymer of a high-melting polyolefin can be formed on this catalyst either prior to its introduction into the reactor, or at the end of the main polymerization stage [301]. Overall reaction cycles are shortened when the catalyst is first subjected to prepolymerization as a concentrated slurry in a separate reactor to generate the high-melting polymer. This procedure yields a supply of treated catalyst ready for use in the main reactor without delays caused by the low-activity monomer. Sometimes this simple technique yields prepolymer which is poorly dispersed. The problem is reportedly overcome [309] by first polymerizing a small amount of 4MP on the catalyst before adding monomer to generate nucleating polymer. An even simpler procedure apparently works: If a mixture of 4MP and the preferred monomer for nucleation is used for prepolymerization, 4MP is consumed first because of its higher reactivity, leaving the virtually pure second monomer free to polymerize on the expanded catalyst particles. Less than 1 % of this additive is needed.

Following the addition of (prepolymerized) catalyst to the main reactor, an initial charge of 4MP and comonomer establishes both the required composition and the polymerization rate, which is first order with respect to catalyst and monomer. As polymerization proceeds at ca. 60 °C, continuous injection of monomers maintains the reaction conditions until the prescribed amount of polymer has formed. This reaction lasts a few hours, during which small injections of hydrogen control molecular mass, as in polypropylene manufacture. Termination of monomer feeds, followed by a short run-down period ensures that most of the monomer is consumed before deashing starts.

All catalyst components are solubilized by adding a C_3 – C_6 alcohol to the slurry in a second heated vessel. Centrifuging, followed by several stages of washing with alcohol – diluent mixtures extracts catalyst residues and soluble polymer. Importantly, addition of water, used in some polypropylene deashing processes, results in lower transparency of molded articles. Ash levels below 0.01 %, and < 10 ppm of Al and Ti are readily achieved. All filtrates are recycled after separation by fractional distillation.

Conventional hot-nitrogen driers remove diluent from the centrifuged cake. After addition of stabilizers, the dry powder is densified at 270 – 300 °C in an extruder with a length/diameter ratio of about 30/1. Various grades differ in comonomer content, molecular mass, and additive formulation (e.g., reinforcement with glass fibers, mica, and mineral fillers).

A Mitsui patent [314] describes techniques for making broad MMD (co)polymers from 4MP using $MgCl_2$ supported catalysts in a two-stage polymerization system. This can be either conventional diluent-based slurry for each stage, or slurry for the first stage followed by a fluidized-bed reactor operating at 100 °C and 0.2 MPa absolute pressure.

In 1989, Phillips Petroleum commissioned a 250 t/a integrated pilot plant at Bartlesville, United States, making 4MP monomer to convert into PMP for evaluation and sale. This plant operates a slurry process using a conventional semibatch stirred reactor.

Patents to BASF [315], [316] describe bulk polymerization of 4MP at 90 – 150 °C under inert gas pressures up to 2 MPa to increase the yield. Catalysts used were $TiCl_3 \cdot AlCl_3$/tributyl phosphine/$AlEt_2Cl$. Hot-heptane solubles of ca. 30 % were, however, high, and no process has yet been announced.

Institut Français du Petrole's intriguing isomerization – polymerization of potentially cheap 4-methyl-2-pentene to PMP, using $TiCl_3$, nickel acetylacetonate, and $AlEt_2Cl$, has not been commercialized [317], [318].

5.3. Polymer Structure

5.3.1. *Homopolymer*

PMP polymer, made with highly isospecific catalysts, has the following regular head-to-tail structure in which all isobutyl groups lie on one side of the chain in a two dimensional Fischer projection.

NMR spectroscopy, so useful in polypropylene and ethylene – propene copolymer characterization, is of limited use for higher poly (α-olefins) where overlapping resonances of the main- chain atoms and pendant groups severely impair resolution and interpretation [319]. Deductions concerning polymer stereoregularity largely rely on crystallinity related phenomena, such as X-ray and IR spectra, melting behavior, solvent fractionation, and various physical properties.

Stereoregular poly(α-olefin) chains pack together to form high-melting crystallites, which then assemble into a superstructure of radially symmetric spherulites during crystallization from a melt phase. In unbranched polyethylene, the chains adopt a zig-zag arrangement in the crystal. The methyl side group in polypropylene forces the chain to adopt a helical configuration involving three monomer units per turn (3/1 helix). With still larger branches the helix unwinds to 4/1. In the case of PMP, the bulky isobutyl group is accommodated in a 7/2 helix with 3.5 monomer units in each turn, and four chains per unit cell of 28 monomer units. Unit cell parameters are $a = b = 1.86$ nm and c (chain axis) = 1.38 nm [320]. This gives an exceptionally low calculated crystal density of 0.822 ± 0.006 g/cm^3, largely because of the loose space packing of helices. At room temperature, the amorphous phase in this semicrystalline polymer has the higher density of 0.838 g/cm^3 [320], [321]. In a typical molding, the average polymer density of PMP is ca. 0.83 g/cm^3. Such a unique reversal of crystalline and amorphous polymer densities has some interesting implications for molding operations. At 60 °C, a common mold temperature, the densities of the two phases are judged to be equal, i.e., there would be no volume change for crystallization at this temperature.

Crystalline PMP finally melts at about 250 ± 5 °C (slow heating) and has a glass transition temperature T_g of 50 – 60 °C at 100 Hz [312] (18 – 30 °C by dilatometry [321]). Other transitions have been reported [322]: 130 °C (start of crystal disordering) and at – 120 °C to – 150 °C (relaxation of short chain segments). Crystallization from the melt does not require massive supercooling. Isothermal crystallization half time at 220 °C is 0.5 min, increasing to 480 min at 236 °C. As with polypropylene, PMP is properly viewed as a semicrystalline polymer, achieving a crystallinity of ca. 75 % in fully annealed samples, 40 % in quenched moldings, and 55 – 65 % in normally fabricated articles [323]. The only stable crystallite formed from polymer melts is tetragonal, but up to five polymorphs can be obtained by crystallization from solution [324].

5.3.2. *Copolymers*

Random copolymers of 4MP, with ca. 2 – 8 wt % of C_6 – C_{12} linear α-olefins, are important commercially because of their good transparency and robust processing behavior.

All linear α-olefins copolymerize with 4MP to some degree. Products are complex, with a single copolymer preparation yielding chains with a wide range of compositions and degree of block structure. The more active comonomers, such as ethylene and propene, produce a dispersed phase of slightly modified PE or PP, even when only 5 mol % of the comonomer is fed [325]. The amount of this phase increases as more comonomer is used, thereby further reducing transparency through light scattering. 1-Hexene and a few other comonomers behave differently in that they are able to substitute for 4MP units in the crystal without significantly distorting or altering the crystal structure of PMP; nor do they generate a second dispersed phase [326]. In these cases, the physical properties still resemble those of PMP at low comonomer contents. Small decreases in crystallinity and melting point are measurable but they are less severe than with non- cocrystallizing monomers. 1-Pentene copolymers also readily cocrystallize, causing some slight lattice contraction. Only small proportions of 1-butene can be accommodated within the lattice.

Increasing the monomer chain length to octene, decene, and above makes cocrystallization increasingly difficult. However, small amounts of 1-octene and 1-decene are accommodated within the lattice by expansion, but octadecene is far too large. The latter monomer severely reduces crystallinity and forces the copolymer into amorphous regions. The magnitude of these crystal changes is detailed in [326]. α-Axis spacing in cocrystallized copolymers can expand from 1.86 to 1.91 nm with octene, and shrink to 1.81 nm with 1-pentene copolymers.

Glass transition temperature is favorably reduced by 15 – 20 °C in 5 mol % 1-decene copolymers. This in itself is only sufficient to give a small toughness improvement because of the high T_g of PMP homopolymer. Copolymerization usually lowers the modulus.

5.4. Properties of PMP Products

5.4.1. *Optical Properties*

Crystalline PMP polymers exhibit unusually high optical transparency, both in terms of clarity (narrow-angle scatter) and haze (high-angle scatter). Optical transmittancies of commercial resins are in the region of 90 – 95 %, compared with 88 – 92 % for polystyrene and 90 – 92 % for acrylics. Other, more familiar crystalline polyolefins, such as polyethylene and polypropylene, are at best translucent in thin sections. In these cases light is scattered from spherulitic assemblies of crystalline and amorphous regions that have different optical refractivities. Additionally, the crystallites themselves are anisotropic.

With spherulitic PMP, high transparency is favored by the similar densities of the crystalline and amorphous regions, and by the low optical anisotropy of helical chains in the spherulites. Providing polymers have been thoroughly deashed, homopolymer optical transmittances of 80 – 85 % can be realized in quenched, 3 mm thick moldings, and > 90 % in 1.5 mm thick samples. Plaques cooled more slowly develop considerable haze and lower transparency (20 %) as a result of increased interspherulitic voiding. These voids, about 1 µm in diameter, cluster round the boundaries of spherulites in the form of “shells” which are responsible for haze [327]. Quenched moldings have fewer microvoids because crystallization takes place at lower temperatures. This lowers the volume reduction on crystallization as the densities of amorphous and crystalline phases become more similar. At this lower temperature, the stronger melt is more able to resist shrinkage stresses without forming voids.

Copolymers of the type described in Section Copolymers have improved transparencies because of such reduced voiding. With these products the crystallization temperature is reduced by 10 – 30 °C, depending on composition, giving improved transparency in both quenched and slowly cooled moldings. With 11 wt % 1-octene copolymer, the transmittance increases to 91 % and 85 % in 3 mm thick quenched and slowly cooled moldings, respectively. This improvement with copolymers is useful, even with 5 wt % comonomer, because high transparency then becomes less dependent on maintaining very precise molding conditions. It is interesting to note that spherulite size is largely unaffected by copolymerization, or by quenching a molding [328], except in the thin surface skin.

The final, but major improvement to optical transparency comes from introducing properly dispersed nucleating agents into homo- or copolymers to reduce the size of spherulites from 50 µm to < 5 µm. In quenched, nucleated homopolymers optical transmission reaches 96 %, which only falls to about 88 % with slower cooling (Tables 29 and 30). Copolymers, already quite transparent when quenched, now achieve transmittancies around 96 % in slow- cooled moldings after nucleation (Table 30). The combination of nucleation, rapid cooling, and copolymerization virtually eliminates microvoiding in most moldings.

Table 29. Optical transmission of PMP homopolymer with poly(4,4-dimethyl-1-pentene) nucleant [309]

Spherulite size, µm			Transmission of
Max.	Mean	Min.	quenched moldings, %
100	50	< 1	69
15	10	< 1	86
< 1	< 1	< 1	96

Table 30. Copolymer nucleation [a] with poly(3-methyl-1-pentene) [309]

Comonomer	Optical transmission, %			
	Quenched moldings		Slow-cooled moldings	
	No nucleant	Nucleated	No nucleant	Nucleated
1-Pentene [b], 2 wt %	84	97	40	94
1-Hexene [b], 2 wt %	84	97	40	94
1-Octene [b], 2 wt %	84	97	40	94
1-Decene [b], 2 wt %	84	97	40	94
None	84	95	20	88
1-Hexene, 2 wt %	84	97	40	94
1-Hexene, 5 wt %	87	98	72	96

[a] Nucleated samples all had mean spherulite diameters < 2 µm, while unnucleated samples had mean spherulite diameters > 25 µm.
[b] Optical transmission similar for all four comonomers.

Excellent light transmission in the near UV region makes PMP superior to glass and other transparent plastics in this respect, and inferior only to quartz (Figure 53).

Figure 53. Light transmission [329]

5.4.2. *Stability and Chemical Resistance*

The semicrystalline and saturated hydrocarbon nature of PMP confer excellent resistance to polar solvents and inorganic substances, and to strong aqueous solutions of most mineral acids, alkalies, and salts. Vulnerable tertiary C – H bonds make PMP unsuitable for use in highly oxidizing environments, such as chromic acid, concentrated nitric acid, and chlorine. It is permeable to some light hydrocarbons, aromatic liquids, and halogenated solvents, which cause swelling and some loss of strength. Repeated sterilization with superheated steam at 135 °C over 60 cycles causes only minor reductions in mechanical properties [330]. Accordingly, PMP is especially suited to medical uses. None of the alternative transparent polymers (polystyrene, acrylics, polycarbonate, and polyester) can offer PMP's broad range of resistance at room and elevated (60 °C) temperature. Resistance to detergent stress cracking, while better than other transparent polymers, is not quite up to the standard of the best bottle-blowing grades of polyethylene.

Above 100 °C, several aromatic and aliphatic solvents will effect complete dissolution. Stable gels containing 0.5 – 2 mm diameter spherulites form on rapidly quenching cyclohexane solutions containing 150 g/L of PMP [331]. Decalin at 135 °C is suitable for conventional molecular mass measurements by viscometry according to the Mark – Houwink equation [332] $[\eta] = 1.94\times10^{-4} M_v^{0.81}$.

Thermal Degradation. Processing temperatures of ca. 300 °C are necessary for the majority of PMP grades. Even under high vacuum these severe conditions promote degradation as evidenced by a marked decrease in molecular mass and gas evolution [333], principally isobutene (55 %) and propane (35 %). Carbon- carbon bond cleavage occurs in chain reactions in which hydrogen is abstracted from tertiary C–H bonds. The initial high rate seems to stem from a few weak links, possibly resulting from adventitious oxidation. Degradation subsequently continues at a lower rate. Suitable melt stabilizers incorporated by manufacturers severely retard much, but not all degradation.

Thermo-oxidation. Oxygen greatly accelerates the rate of chain scission over heat alone [334-336]. Precautions must be taken not only at high melt processing temperatures, but also in the solid state. Oxidation is accompanied by molecular mass reduction along with hydroxyl and carbonyl formation in the polymer, leading to yellow discoloration, brittleness, and odor at long exposures. Low molecular mass volatiles such as aldehydes, ketones, acids, water, and carbon dioxide form in chain reactions involving peroxidation of tertiary C–H bonds and radical-induced chain cleavage. The well-established faster oxidation of PMP compared to PP is attributed to the more rapid diffusion of oxygen in the open PMP structure. Studies indicate [335] that oxygen also attacks PMP crystallites, and not just the amorphous phase, as in PP.

Stabilizers derived from bulky hindered phenols and polyphenols, phosphites, and thioesters provide reasonable protection against deterioration during processing and in service at elevated temperature. The useful life with ca. 0.2 – 0.5 % of these additives increases from around one day at 200 °C to seven years at 100 °C [337]. Manufacturers advise on the most suitable polymer grade and further appropriate antioxidants for demanding applications.

Photo-oxidation. Photodegradation of PMP is basically similar to thermal oxidation, but UV light of wavelength < 400 nm seriously accelerates decomposition because chromophores, perhaps from impurities or oxygen charge-transfer complexes, assist oxidation by peroxide intermediates. Chain decomposition then yields an array of oxidized products and lowers the molecular mass [338-340]. These reactions can be minimized by incorporating into the polymer specific stabilizers to deactivate excited chromophores, scavenge radicals, and reduce peroxides. Hindered amine light stabilizers (HALS), which behave as UV-stable antioxidants, and metal chelates are quite effective [340]. However, the latter can cause mild blue-green discoloration.

Enhanced oxygen diffusion in PMP is cited as a principal reason for its greater susceptability to photodecomposition than PP. Applications involving extended outdoor weathering need careful appraisal, even with UV-stabilized grades, unless there is heavy protection by pigment screening with carbon black, ferric oxide, rutile, etc. Light reaching earth is screened of wavelengths < 290 nm by the atmosphere.

Suitably formulated PMP is also able to withstand up to 50 kGy of high energy β- and γ-radiation, used for sterilization, without discoloration or embrittlement [341]. Irradiation at higher doses (3 MGy) causes cross-linking and generation of volatiles [342], whereas chain scission is the dominant reaction with PP except at high doses.

5.4.3. *Mechanical Properties*

PMP has mechanical properties reasonably similar to those of PP at 0 – 100 °C. This applies to flexural modulus, yield strength, and hardness, though the precise comparison is dependent on the chosen grade (Table 31). Copolymers are more flexible with lower yield strengths and softening points. Melting and crystallization curves of two commercial copolymer grades, provided by Mitsui Petrochemical Industries (Figs. 54 and 54) illustrate some differences. Figure 54 shows DSC (differential scanning calorimetry) exotherms and endotherms for a lightly copolymerized PMP. While the final melting is at 242 °C, with a peak melting rate at 233 °C, the onset of melting is clearly visible at 200 °C. The second copolymer (Figure 55) is much less crystalline (melting peak areas 28.2 and 37.2 J/g respectively), with a slightly lower final melting point of 231 °C and a peak at 226 °C. This reduction in crystallinity is responsible for lowering modulus, heat deflection temperature, and surface hardness. A presumed lowering of the glass transition temperature accounts for the increased unnotched impact strength of MX004, although this is still inade-quate to raise notched impact strengths at room temperature.

Table 31. Mechanical properties of PMP [a]

Property	Method	Poly(4-methyl-1-pentene)					Polypropylene	
		Crystalor		TPX		Crystalor, TPX	Propathene	
		HBC-020 (homopolymer)	CBN-020 (copolymer)	RT18 (copolymer)	MX004 (copolymer)	30 % glass fiber filled	GWM 22 (homopolymer)	GWM 101 (copolymer)

Density (20 °C), g/cm^3	ASTM D 1505	0.835	0.835	0.833	0.834	1.04	0.905	0.905
Melt flow index (MFI) at 260 °C, 5 kg, g/10 min	ASTM D 1238	20	20	26	26		4.0 [b]	6.0 [b]
Melting point, °C	Manufacturers	240	235	240	240	230 – 240	170	165 – 170

Carefully molded PMP articles are less brittle than transparent polystyrene and acrylics, and they are nearly as tough as polypropylene homopolymer. The latter usually fails with some yielding in unnotched Izod tests at room temperature, thereby giving high failure energies. PMP's higher T_g causes failure in a brittle mode unless it is sufficiently modified by copolymerization. Above 150 °C, PMP has greater strength and form stability than PP and polycarbonate as a result of its high melting point. At 20 °C PMP creeps less in long-term tests than either polypropylene or high-density polyethylene.

Polymers filled with glass fiber and mineral additives are available from Mitsui, Phillips, and Schulman in Belgium. Composites with 30 % glass fiber are particularly useful due to their enhanced modulus and greater form stability at 200 – 250 °C. With 30 wt % glass fiber, room temperature modulus is triple that of PMP homopolymer, while the heat deflection temperature increases from 90 °C to 227 °C (Table 30).

5.4.4. *Electrical Properties*

The excellent electrical insulation properties of PMP (Table 30) are similar to those of PTFE and the best cable-grade polyethylene, whilst in the frequency range of 10 kHz to 20 MHz PMP is superior. Its permittivity (dielectric constant) is the smallest of all synthetic plastics, and it remains essentially constant over wide temperature and frequency ranges. A combination of low dielectric loss factor and good form stability at high temperature makes it very suitable for microwave oven applications. Due to its negligible moisture absorption, PMP preserves these electrical characteristics under adverse conditions.

Table 32. General properties of PMP products

	PMP	PP
Coefficient of linear expansion, K^{-1}	1.17×10^{-4}	1.1×10^{-4}
Thermal conductivity, $Wm^{-1}K^{-1}$	0.168	0.209
Specific heat (20 °C), $Jg^{-1}K^{-1}$	1.97	1.93
Heat of melting[a], J/g	143[b]	185
Burning rate, cm/min	2.54	2.3
Mold shrinkage, %	1.5–3.0	1–2
Refractive index, n_D^{20}	1.463–1.470	1.503
Volume resistivity, $\Omega \cdot cm$	$> 10^{16}$	$> 10^{16}$
Dielectric breakdown voltage, kV/mm	42–65	75
Permittivity at 100 Hz–1 MHz	2.1	2.25
Dielectric loss factor tan δ		
(20 °C) 50 Hz 10^{-6}	60	150
1 kHz 10^{-6}	35–140	200
1 MHz 10^{-6}	25–50	150

[a] For 100 % crystalline polymer.
[b] Mitsui value; for other measurements see [320] [323] [344].

5.4.5. *Surface Properties and Permeability*

PMP's surface tension of only 24 mN/m is the second lowest to PTFE (20 mN/m) [345]. This confers good stain resistance and excellent release properties towards other materials.

Confirmation of PMP's loose space packing is to be found in its high permeability towards gases (Table 30). Oxygen, nitrogen, and carbon dioxide diffuse some 25 times more rapidly through PMP film than through cast PP or HDPE films. Moisture vapor transmission is substantial, despite the low absorption of only 0.01 %, even after total immersion in water.

Table 33. Gas and water vapor permeability of 50 µm PMP film [346]

Permeability to	PMP	HDPE	PP
Oxygen, L m^{-2} d^{-1} atm^{-1}	40	1.1	1.6
Nitrogen, L m^{-2} d^{-1} atm^{-1}	9.5	0.3	0.36
Carbon dioxide, L m^{-2} d^{-1} atm^{-1}	120	4.6	6.5
Water vapor, g m^{-2} d^{-1} atm^{-1}	65	4.0	7.0

5.4.6. *Rheology*

PMP melts are strongly non-Newtonian. Their viscosity decreases rapidly at high shear rates and with increasing temperature (Fig. 56). These two effects produce particularly fluid melts under optimum processing conditions, and they call for some alteration to processing techniques compared to PP. In most cases friction heating alone in the extruder barrel is insufficient for uniform melting, and pressure generation also needs improving. Allowance should be made for low melt strength. There is a suggestion [323] of some melt order in view of the low entropy of fusion, 10.3 J K^{-1} mol^{-1}. The particularly rapid decline in viscosity with increasing temperature, around 280 °C, also has been linked with helical association in the melt [344], [347], [348].

Figure 56. Viscosity curves [347]

a) Polypropylene (Propathene) MFI 4.0 (230 °C/2.16 kg); b) – d) Poly(4-methyl-1-pentene), TPX, grade DX810, MFI 70 (260 °C/5.0 kg)

5.5. Economic Aspects

The following list prices (in £/t) for polymerization grade materials and polymers prevailed in the fourth quarter of 1991:

Propene (Western Europe)	210
4-Methyl-1-pentene	Not traded
1-Hexene	1010
1-Octene	920
1-Decene	900
Polypropylene (Western Europe and United States)	360 – 450
PMP (grade and volume dependent)	2500 – 4300

The higher cost of PMP over PP reflects higher raw material prices without the economies of scale now realized for PP, as well as 10 years difference in experience.

5.6. Fabrication and Applications

5.6.1. *Fabrication*

In principle, most of the normal fabrication techniques used for polyolefins can be used to make PMP articles, provided due recognition is given to its high melting point and low melt viscosity. Further changes to processing techniques have been introduced over the past five years to improve output rates and quality.

Injection Molding. While both piston and screw injection molding machines can be used, the ideal type employs a slow- compression screw with an L/D ratio of 20 – 24. The cylinder must be capable of being heated to 350 °C, with precise temperature control over the preferred operating range of 280 – 320 °C. Friction heating is inadequate, and can cause local decomposition. An alternative is to feed the machine with granules preheated to 130 °C. A valved nozzle prevents die drool between shots with very fluid melts. Injection pressures only need to be 50 and 25 MPa for the primary and secondary stages, with a relatively slow injection speed (< 50 % of the machine capacity) into a mold at 20 – 60 °C. Gas venting of molds is imperative to avoid burning from any volatile decomposition products formed at high melt temperatures.

Extrusion Blow Molding. The attraction of making high-quality transparent containers by blow molding PMP is tempered by poor melt strength and additional heating requirements. Some simple adjustments to secure accurate melt temperature control in the range 220 – 250 °C, the use of a parison controller and accumulator, and pressure generation with a barrier type torpedo are satisfactory for certain applications. Still higher quality and better production rates call for a number of additional alterations. These include continuous parison extrusion, modification of the pinch-off blades, a long L/D extruder, and mold vents. Manufacturers advise on the best conditions for their resins.

Injection stretch blow molding is the ideal method for making high- clarity containers having excellent physical properties due to biaxial orientation (see Section Blow Molding). A standard low- compression screw normally suffices, but improved heating to 200 °C is called for in the conditioning station before transfering to the final mold. Here, the blowing air must have a supply pressure of 3 MPa. Standard machines are easily modified to process PMP.

Extrusion. PMP can be used in most plastic extrusion processes for making film, fiber, sheet, pipe, and coatings for wire and paper. In all cases the extrusion stage should have ample barrel heating arrangements. Twin and single conventional full-flighted or three-stage screws used for PE or PP are suitable, provided that those generating excessive shear are avoided. However, the throughput is reduced with PMP, and surging tends to occur when the screw speed is increased. A more suitable single screw has a double flight in the compression zone to separate melt and solid polymer before it is plasticized (Fig. 57). This secures stable operation without any throughput penalties.

Figure 57. Screw for PMP [349]

$L/D \geq 28$; $CR = H_f/H_m = 2.5 – 3.0$; H_f = Depth of feed zone; H_m = Depth of metering zone

The downstream equipment used for making sheet, film, tubes, and coatings is similar to that used for PP, but with appropriate temperature adjustments. Fine fibers can be made by the blown melt method or by the long spin process (see Section Fibers and Flat Yarns).

Difficult and Impractical Processes. Thermoforming, either by vacuum, pressure, or matched-mold processes is difficult, but possible, with PMP thin sheet. The need to use high temperatures, followed by a long cooling period gives a cycle time of approximately 1.5 min. However, attractive food trays for microwave ovens are being made from thin sheet by using low draw down ratios. Rotational molding and mechanical forming are unsuited to PMP. Small amounts of foamed moldings are marketed.

5.6.2. *Applications*

The sales pattern of PMP worldwide in 1991 is reported by Mitsui Petrochemical Industries (MPC) as follows [350]:

Release film and paper	22 %
Industrial	20 %
Medical and laboratory	13 %
Cookware	11 %
Electric	7 %
Packaging	6 %
Others	21 %

PMP film, manufactured by MPC under the trade name Opulent, is available in different thicknesses (25 – 500 µm), with different flexibilities (modulus 0.7 – 1.6 MPa), and with alternative surface finishes. Three-layer laminates with Kraft paper or low-softening polyolefins extend the range. These products find extensive use in applications requiring good release characteristics combined with high temperature resistance and chemical inertness. Important examples include release films in manufacturing electronic circuit boards, in curing advanced composites for aircraft parts, and in continuous curing of rubber with heat or by UHF vulcanization. Inert mandrels made from flexible grades of PMP are used as supports during the manufacture and curing of reinforced high-pressure rubber hoses.

Good electrical properties and heat resistance meet specifications for use as covering for heat resistant wire, power, oil well, and communication cables. Glass-fiber-filled grades have sufficient shape retention after a few minutes at 260 °C to be used in dip soldering applications. Other industrial uses include replacement of stainless steel chemical treatment trays, sight glasses and floats, and a multitude of electrical insulators.

Labware and medical products were the first to take advantage of PMP. Transparency, convenience of sterilization with either γ-rays, ethylene oxide, dry heat, or steam autoclaves, and resistance to soiling are all relevant. Examples include blood test cells, medical instruments, tubing connectors, centrifuge cups, syringes and other measuring devices, urine collection tubes, and blood transfusion equipment. In the laboratory, PMP cages for small animals are easily cleaned and sterilized. Shatterproof transparent replacements for glass embrace most of the familiar items such as beakers, measuring cylinders and jugs, funnels, bottles, and Petri dishes.

Important outlets exist in food preparation where resistance to heat, oil, and steam is needed. Baking trays for bread, and thermoformed PMP- coated paper cartons for cooking foods, either in microwave or sometimes in gas-heated ovens, have superior releasability to aluminum foil containers. Application extend to coffee maker parts, popcorn popper covers, packages suitable for food retorting, microwave oven cookware, and service trays.

New areas under investigation include outlets for PMP fibers, such as nonwoven fabric, gas separation systems, and optical fibers.

5.7. Health and Environmental Aspects

PMP itself is regarded as inert and nontoxic, like polyethylene and polypropylene. Formulation systems for various grades are available to conform with food regulations in Japan, Germany, the United States, and the United Kingdom. Being a saturated hydrocarbon, PMP presents no problems in disposal by complete combustion. Flammability is the same as for PP. In principle, PMP can be recycled for reuse in similar or lower-quality applications, but attention must be paid to molecular mass reduction as a consequence of high-temperature processing.

1. Introduction

This article deals with polyoxyethylene, polyoxypropylene, and polytetrahydrofuran or poly(1,4-epoxybutane). Other names include poly(ethylene oxide), PEO; poly(propylene oxide), PPO; and poly(tetramethylene oxide), PTMO. Strictly speaking, the latter polymer is not derived from an alkene and thus is not a poly(alkylene oxide); however, it is included here, and the term poly(alkylene oxides) is used as a collective term for these three polymers. The poly(alkylene oxides) have an ether linkage in their main chain backbone and thus are polyethers. They are described by the repeat unit

$$-[(CH_2)_x-CHR-O]-$$

Poly(ethylene oxide):	R=H, x=1
Poly(propylene oxide):	R=CH_3, x=1
Poly(tetramethylene oxide):	R=H, x=3

Many details about the alkylene oxides and their polymers are given in [1].

2. Properties

Physical Properties. Typical physical properties of PEO, PPO, and PTMO are presented in Table 1. Except for PTMO, these polyethers can be linear or branched and are commercially available in a broad range of molecular masses from less than a few hundred to several million.

Low molecular mass polymers of ethylene oxide are clear, essentially colorless liquids and become partially crystalline solids at a molecular mass of ca. 800. As the molecular mass increases, they change from soft waxy solids to hard waxes. At high molecular mass, they are tough thermoplastics. Polyoxyethylenes of less than ca. 20 000 number-average molecular mass are usually referred to as poly(ethylene glycols). The crystalline polymer is spherulitic, has a unit cell (see Table 2) with four molecular chains, and has a fiber identity period of seven repeat units in two helical turns. The molecules are in an array of dihedral symmetry with twofold axes. One axis bisects the carbon–carbon bond and the other passes through the ether oxygens.

The glass transition temperature of PEO is listed as -52 °C in Table 1; however, this is the value for a high molecular mass, partially crystalline polymer. This parameter is complicated by crystallinity in the molecular mass range 10^3–10^5 [22], and abnormal values as high as -17 °C are found for the polymer with M = 6000, which is known to have the highest crystallinity (ca. 95 %). Macrospherulites or spherulites that can be seen without magnification have been prepared [23].

PEO is soluble in water, chlorinated hydrocarbons, aromatic hydrocarbons, methyl ethyl ketone, 2-ethoxyethyl acetate, butyl acetate, cyclohexanone, esters, dimethylformamide, and

other solvents [1]. It has a solubility parameter of 10.3 [24]. It is insoluble in ethers and aliphatic hydrocarbons. Mark – Houwink constants for the intrinsic viscosity/molecular mass relationship $[\eta]=KM^a$ are given in Table 3. In water, PEO exhibits an inverse solubility – temperature behavior, becoming less soluble as the temperature is increased.

Intermolecular or association complexes between PEO and other compounds are readily formed due to the strong hydrogen bonding character of the ether oxygens. These complexes, which involve PEO and polymeric acids such as poly(acrylic acid) [35], urea, and thiourea [36], as well as various other inorganic and organic compounds [1], [37], have potential applications

in mechanochemical energy conversion systems [38], chemical valves for altering the porosity of membranes [39], and biosensors and carriers for controlled drug delivery [40]. Alkali-metal salt complexes have electrical properties that make them of interest as battery electrodes [41].

Polymers of propylene oxide remain clear, almost colorless liquids or amorphous solids over broad ranges of molecular mass. They can be prepared as amorphous or stereoregular polymers, with stereoregularity resulting in crystallinity. Polyoxypropylenes with $M <$ ca. 20 000 are usually referred to as poly(propylene oxide) polyols, and these polymers are by far the most important products from a commercial standpoint. They are usually marketed as di- and trihydroxyl polyols that are available in a broad range of molecular mass. (The third hydroxyl group comes from the initiator; for example if glycerine, which is the most common initiator for PPO polyols, is used, the PPO grows off all three hydroxyl groups and a trifunctional polyol results.) High molecular mass PPO polymers are used as specialty rubber and represent only a small worldwide demand of about 1000 t/a. The crystalline polymer has a unit cell (see Table 2) that contains two chains in a bowed zigzag conformation, with the methyl group of one molecule located between the ether oxygen and methylene group of the adjacent molecule.

PPO is soluble in most organic solvents. Very low molecular mass polyols (< 1000) are insoluble in aliphatic hydrocarbons such as hexane due to the high hydroxyl content. However, polyols with such high hydroxyl contents do have some solubility in water. Mark – Houwink constants for the intrinsic viscosity/molecular mass relationship $[\eta]=K M^{a}$ are given in Table 3.

Although not so thoroughly studied as those of poly(ethylene oxide), association complexes of poly(propylene oxide) are also known. These complexes are formed with a variety of salts such as lithium perchlorate [42] and metal halides, particularly chlorides [43]. Complexes of propylene oxide – ethylene oxide block copolymers with sodium and lithium salts exhibit marked increases in electrical conductivity [44] as compared to the uncomplexed copolymers.

Tetrahydrofuran can be polymerized to high molecular mass, but the commercially available poly(tetramethylene oxide) diols have molecular masses of ca. 650 – 3000 and a narrow molecular mass distribution. Although these polyols are usually crystalline in nature, their narrow molecular mass distribution [45] makes them easy to use, since even partial melting yields a product with effectively the same molecular mass distribution as that of a completely melted product. The crystalline polymer has a monoclinic unit cell whose characteristic dimensions are given in Table 2.

Solvents for PTMO, which has a solubility parameter of 17.3 – 17.6 [46], include aromatic hydrocarbons such as benzene and toluene, chlorobenzene, dichloromethane, chloroform, carbon tetrachloride, esters such as ethyl acetate, and nitrobenzene. Low molecular mass products are soluble in acetone, alcohols, and similar polar solvents. The polymers are insoluble in aliphatic hydrocarbons such as heptane, hexane, pentane, and petroleum ether. Only cursory studies of association complexes of PTMO have been conducted [43].

Chemical Properties. Poly(alkylene oxides) are chemically characterized as usually having primary (PEO and PTMO) and secondary (PPO) hydroxyl end groups [47]. PEO and PPO have been prepared with a variety of end groups including allyl or propenyl ethers, which arise during polymerization of ethylene oxide and propylene oxide through the termination reaction [48]; carboxyl [49], [50]; amine [51]; cyano [52]; and vinyl ether [53]. Alkyl or aryl ester terminated PEOs are used as nonionic surfactants [54], [55], and alkoxy-terminated PEOs prepared from alcohols or other monohydroxyl compounds are used for similar purposes as well as in cosmetic and pharmaceutical preparations. In addition to primary hydroxyl termination, PTMOs have been prepared with a majority of primary amino terminal groups [56]. Isocyanate-terminated poly(propylene oxides) and poly(tetramethylene oxides) are known as isocyanate-terminated prepolymers for preparation of polyurethanes.

Copolymers of various types can be prepared from the alkylene oxides. The best known of these are the polyurethanes, though they are not normally prepared from the poly(ethylene oxides). Polyurethanes are formed in a rearrangement reaction from poly(alkylene oxide) polyols, short chain diols such as 1,4-butanediol and ethylene glycol, and multifunctional isocy-

anates. The reaction takes place at relatively low temperatures, including room temperature, as depicted in the general, idealized manner (Fig. 1) where Y represents the residue of a polyfunctional isocyanate without its isocyanato groups. (In this generalization, it should be noted that the starter molecule for the poly(alkylene oxide) is omitted. If the alkylene oxide involved were propylene oxide, on the average both end groups would have been secondary hydroxyl groups.)

This unit would be the average repeating unit in the final polyurethane. A wide variety of isocyanates are used, including toluene-2,4-diisocyanate, 4,4′-diphenylmethane diisocyanate and its polymeric forms, 4,4′-dicyclohexylmethane diisocyanate, and isophorone diisocyanate. The latter two isocyanates are used when light-stable polyurethanes are required.

Urethane acrylates are formed by preparing an isocyanate-terminated prepolymer and then capping it with a hydroxyalkyl acrylate. These acrylate-terminated oligomers are widely used in radiation curable coatings.

Isocyanate-terminated PTMO polyols have been marketed as Adiprene (Du Pont) and Vibrathane (Uniroyal) precursors. Block copolymers of poly(tetramethylene oxide) and poly (butylene terephthalate) are marketed as Hytrel (Du Pont) for a variety of end uses.

Other copolymers include the very important ethylene oxide – propylene oxide copolymers [57], which occur in random, block, and graft form. Random copolymers are usually prepared from mixtures of monomers, and block copolymers by alternately feeding the two monomers. Block copolymers are often used as surfactants, metal lubricants, and functional fluids. Most of the block copolymers have poly(ethylene oxide) as the hydrophilic block and poly(propylene oxide) as the hydrophobic block. Other hydrophobic blocks include poly(styrene oxide), poly(tetramethylene oxide), and polystyrene [58]. ABA block copolymers of poly(1-proline) and amine-terminated PEO [59], as well as those of poly(ε-caprolactone) [60] and polyesters [61] grown onto hydroxyl-terminated PEO, have been prepared. A well-known graft copolymer, hydroxyethyl cellulose (→ Cellulose Ethers, Chap. 5.1.1.) [62], [63] is formed by swelling cellulose in a caustic solution and then adding ethylene oxide to the hydroxyl groups of the anhydroglucose units. Silica [64], gelatin and collagen [65], and chitin [66] are other polymeric substrates to which ethylene oxide has been grafted. Low molecular mass PEOs terminated with 1,2,4-triazoline-3,5-dione have been grafted onto polybutadiene [66].

A particularly useful class of grafted poly(propylene oxide) polyols was discovered in 1966 [67], [68]. These so-called polymer polyols are composed of vinyl polymers (e.g., acrylonitrile, styrene) and copolymers which are grafted to PPO or to PEO- capped PPO. They are produced by adding the vinyl monomers to the PPO polyol and dispersing them by agitation. A catalyst is then added to polymerize the vinyl monomers, which are believed to graft or partially graft to the polyol. The polymer polyol retains the end-group hydroxyl functionality, which is thus available for reaction with, for example, isocyanates. The vinyl polymer, which is incompatible with the polyol, is present in the form of a stable dispersion that acts as a reinforcing filler. These polymer polyols are used to manufacture polyurethane foams that have enhanced moduli while maintaining other desirable characteristics. Commercial products contain either grafted polyacrylonitrile or acrylonitrile – styrene copolymers, and they are used in high-resiliency automotive seating [69], microcellular elastomers [70], and other high-performance applications.

A deficiency of polyethers is their susceptibility to oxidation. PEO degrades by an autoxidation mechanism that is associated with formation and cleavage of intrachain hydroperoxides [71], [72]. Mechanical actions such as high shear can also cause degradation [73]. Hydroperoxide formation is facilitated by heavy metal ions, strong acids, and ultraviolet light. PPO and PTMO degrade by both chain scission and crosslinking [74], [75].

A number of investigations indicate that aromatic compounds such as substituted phenols, cresols, and quinones [76–78], mixtures of aliphatic amines and dihydric phenols (e.g., hydroquinone, *tert*-butylhydroquinone) [79], carbamates [80], and similar compounds function as stabilizers. A prime stabilizer for the poly(alkylene oxides) is 2,6-di-*tert*-butyl-4-methylphenol. Stabilization during storage is usually effected with 200 – 300 ppm of the stabilizer. However, in end uses involving solutions or slab stock polyurethane foam produced in

Figure 1. Formation of polyurethanes

bun form [1, p. 237] from poly(propylene oxide) polyols, 1000 – 5000 ppm are used to compensate for the long times at high temperature that are encountered due to retention of the heat of polymerization caused by the excellent insulation properties of the foam.

3. Production

Ethylene oxide was first polymerized in 1863 by Wurtz [81], who heated the oxide with water in a sealed tube. Earlier, in 1859, Lourenço [82] had obtained the polymer from ethylene glycol and ethylene bromide. Seven decades later Staudinger and Lohmann [83] prepared a number of polymers with a variety of catalysts, including alkali and alkaline earth metals.

There are three main ring-opening reactions for the polymerization of ethylene oxide and propylene oxide: acid, base, and coordinate initiation. Acid or cationic initiation [84–86] with an acid, HZ, involves addition of an active-hydrogen compound such as an alcohol or glycol, $(HO)_mX$ (m=1 – 4), to the 1,2-epoxide ring. In the initiation step, an oxonium complex forms and ring opening takes place by cleavage of the oxygen – carbon bond to form an initiated species that is available for propagation.

In the propagation step, n molecules of oxide are added to give a polymer having the formula $HO-[(CHRCH_2O)_n]_m-X$. Termination can occur by proton transfer, which yields an unsaturated product, or by anion transfer, which generates the starting acid.

Brønsted or Lewis acids such as $AlCl_3$, $SnCl_4$, PF_6, and BF_3 are used as initiators. The reaction is very fast, molecular mass is relatively low, and molecular-mass distribution is broad.

Base or anionic initiation [87–89] takes place in the following manner, where R′ is usually an alkyl group.

Propagation takes place in a manner similar to that described above. Termination can be by hydrogen abstraction from the backbone, which results in terminal unsaturation and formation of a new initiation site, or by rearrangement of the active species.

Polymerization rates for the two mechanisms when perchloric acid and sodium methoxide are used are given in Table 4 for a few selected alkylene oxides.

Table 4. Polymerization rate for selected alkylene oxides relative to ethylene oxide [90], [91]

Oxide	Initiator	
	Perchloric acid	Sodium ethoxide
Epichlorohydrin	0.065	4.8
Ethylene oxide	1.0	1.0
Propylene oxide	54	0.5
Isobutylene oxide	5100	0.06

Anionic initiators are usually metal alkoxides such as sodium or potassium methoxide or ethoxide. The reaction is usually slower than that obtained with acid initiation, except for epichlorohydrin and glycidol [90], [91]; relatively high molecular masses can be obtained and the molecular mass distribution is relatively narrow.

Ionic coordinative polymerization [92–95] involves a complex of a metal, M, such as Al, Sn, Fe, Mg, Li, etc., with ligands, L (e.g., OH, OR, Cl) that coordinates in an ionic manner with the oxygen atom of the epoxide. Complexation is followed by nucleophilic attack by the ligand, which results in opening of the oxirane ring to

give an initiated species that can undergo propagation to form the polymer chain.

There are two categories of ionic coordination initiators [94], [96]. Initiators in the first category involve the formation of metal – oxygen coordination bonds, and those in the second category are alkaline earth compounds that have an anionic surface capable of coordinating with the oxide monomer.

In the case of propylene oxide, the monomer has an asymmetric carbon atom (C∗)

and when the ring is opened this asymmetric center is incorporated in the polymer chain. PPO can contain both head-to-tail and head-to-head sequences.

The head-to-tail sequences are formed by the expected carbon – oxygen cleavage between the methylene group and the oxygen atom of the epoxide, whereas the head-to-head sequences occur when unexpected cleavage takes place between the methyl-substituted carbon and the oxirane oxygen. Up to 30 % head-to-head structure has been found in certain polyoxypropylenes [97], [98].

Tetrahydrofuran was first polymerized by Meerwein and Kroning in 1937 [99], [100]. An I.G. Farbenindustrie patent [101] indicates that polymers of this monomer were the subject of numerous investigations from 1939 to 1943. Ring strain, a necessity for favorable polymerization, is small in this monomer compared to other cyclic ethers [102], and thus THF has less tendency to polymerize than ethylene oxide and propylene oxide. Although commercial polymers are dihydroxyl functional and low in molecular mass, a high molecular mass polymer with a melting point above 100 °C has been reported [103].

THF is a nucleophilic monomer that forms a tertiary oxonium ion during initiation and only polymerizes by a cationic ring-opening mechanism [104–108]. A variety of mechanisms for formation of the tertiary oxonium ion are known. These include direct alkylation or acylation, in situ formation from reactive organic halides and metal salts or Lewis acids, and direct addition of strong protic acids to the oxygen atom. For example [109], direct alkylation of the monomer by exchange with trialkyloxonium salts illustrates the initiation reaction.

Propagation then takes place by collisions between the initiated species and THF, whereby

only collisions that occur at the α- carbon atom of the THF molecule result in propagation.

Water, oxygen, and other nucleophilic reagents can be used to terminate the polymerization.

Industrial poly(tetramethylene oxides) are hydroxyl terminated, and control of the termination reaction is important to the process. Hydroxyl groups, which have a profound effect on molecular mass, can be formed if strong protic acids are used to form the initiated species [110], [111]. The proton gives rise to an hydroxyl group on the end of the propagating species, and when water is used to terminate the polymerization, a second hydroxyl group is formed and the initiator acid is regenerated.

4. Toxicity [112]

Poly(ethylene oxides) have a very low single-dose oral toxicity that decreases with increasing molecular mass. Single-dose oral LD_{50} values in g/kg, for polymers of 200, 1000, 2000, and 6000 are, respectively, 34, 45, 45, and > 50 for male rats; 28, 32, > 50, and > 50 for female rats; 14, (not available), > 50, and > 50 for male rabbits; and 34, > 50, > 50, and > 50 for mice. PEOs of 400, 1540, and 4000 molecular mass were fed to dogs at a 2 % level in the diet with no adverse effect. When fed to rats at 2 %, PEO of 400 molecular mass had no effect, and at 4 % PEOs of 1540 and 4000 molecular mass had no effect. Doubling the dietary amounts for rats resulted in weight loss, an increase in liver weight, and slight histologic changes in the liver with the 400 compound, an increase in liver weight with the 1540 compound, and weight loss with the 4000 compound. Feeding of a 4 000 000 molecular mass compound at 5 % (rat) and 2 % (dog) diet had no detectable effect after 24 months. Testing with a radioactively labeled sample of the high molecular mass PEO indicated no significant absorption of the polymer from the gastrointestinal tract of the rat or dog.

PEOs do not appear to cause appreciable irritation to the eyes of rabbits. Skin irritation is apparently absent, which is attested to by the wide use of these compounds in cosmetic preparations. Overall, there are no reported adverse effects or human injuries from handling of PEOs [111].

Poly(propylene oxides) of molecular mass ca. 200 – 2000 have a single-dose oral toxicity that is noticeable, and they have mild eye irritability. They are not irritating to the skin, and even though there is some absorption through the skin, they do not appear to present a serious industrial health hazard. Inhalation of mists, particularly of the low molecular mass compounds (ca. 400 to 1200), could be hazardous. The low molecular mass compounds are rapidly adsorbed from the gastrointestinal tract and are potent CNS stimulants that readily cause cardiac arrhythmia. Excitement and convulsions are apparent within minutes after oral administration. Higher molecular mass compounds (> 2000) are very low in toxicity by all administration routes and do not stimulate the CNS. Oral LD_{50} values (rat) in g/kg for polymers of 400, 1200, and 4000 molecular mass are 1.6, 1.4, and > 15 for males and 2.1, 1.1, and > 15 for females, respectively.

Poly(tetramethylene oxides) are commercially available in four number-average molecular masses (650, 1000, 2000, and 2900) as dihydroxyl functional compounds [113], [114]. Acute oral toxicity (LD_{50} in g/kg) for albino rats was 11.3, 18.8, and > 34 for the 650, 1000, and 2000 molecular mass polyols, respectively. Acute dermal toxicity in albino rabbits was 8.37, 10.25, and > 10.25 g/kg for the same polyols. The poly-ols are rated as being minimally irritating to the eyes and skin of albino rabbits [112]; however, a Material Safety Data Sheet indicates that the products may irritate the skin and eyes [115].

5. Handling

Most manufacturers and suppliers of poly (alkylene oxides) have detailed, handling methods available for bulk, drum, and laboratory handling and storage, which should be consulted when working with the chemicals.

The poly(ethylene oxides) range from liquids at low molecular mass to hard waxes at moderate molecular mass, and to tough thermoplastics at high molecular mass (> ca. 100 000). They are not corrosive to most common construction materials. Although not strongly corrosive to copper and its alloys, some discoloration may occur if the compounds are kept in contact with copper- containing materials for prolonged times. Aqueous solutions of PEOs are corrosive to regular carbon steel; hence, stainless steel should be used for their storage. Tanks for bulk storage are usually made of plain carbon steel.

For smaller quantities, lined steel drums are used to minimize the pickup of traces of iron [116]. When short storage times of a month or less are involved, storage under air is acceptable. For prolonged storage, particularly in hot climates or under heated conditions, the products should be kept under an inert (nitrogen) atmosphere. Since PEOs are hygroscopic, dry conditions are important for most uses. PEOs have low vapor pressures and are not fire hazards unless high temperatures are involved. For example, polymers of molecular mass 200, 1000, 4000, and 9000 have Cleveland Open Cup flash points of 171 – 182 °C, 254 – 265 °C, 271 °C, and 271 °C, and Cleveland Closed Cup flash points of > 148 °C, > 177 °C, > 177 °C, and > 177 °C, respectively.

The poly(propylene oxides) are usually liquid, stable, noncorrosive compounds that have a very low vapor pressure. They are preferably stored at temperatures below 50 °C, usually in carbon steel tanks. However, if there is concern about the pickup of iron, tanks protected with a baked phenolic coating can be used [117]. PPOs should be blanketed with dry air or nitrogen to prevent absorption of moisture during storage. They are usually dried before use in polyurethane manufacture. Nitrogen is preferred for prolonged storage or storage at elevated temperature. They represent fire hazards only at high temperatures. For example, 400, 2000, and 4000 molecular mass polymers have Cleveland Open Cup flash points of 166 °C, 229 °C, and 229 °C, respectively.

The poly(tetramethylene oxides) are liquids or low-melting solids under ambient conditions. Mild steel and phenolic-lined steel tanks are suitable for storage. These products are not considered fire hazards unless high temperatures are encountered, and they have a Tag Open Cup flash point of > 163 °C. The compounds are unstable and may decompose at temperatures above 100 to 200 °C or at lower temperatures if in contact with high surface area substrates such as fibrous insulation [115]. When they decompose, very flammable tetrahydrofuran and carbon monoxide can be released.

6. Uses

Low molecular mass poly(ethylene oxides) (M <800) are usually used as intermediates for the manufacture of fatty acid ester surfactants that are used in a variety of formulated products. Illustrative of these products are soap or detergent suds control agents, foam stabilizers, fabric softeners, and optical brighteners. Typical detergents contain up to 20 % of a nonionic or anionic surfactant. Polymers with molecular mass of ca. 1000 – 2000 are low-melting waxes used in pharmaceutical ointments, cosmetic creams, and lotions. Their low toxicity, nonirritating nature, and smooth, creamy texture along with liquefaction at body temperatures make them particularly useful in cosmetic and pharmaceutical applications such as formulations for salves, suppositories, and ointments. Esters of these compounds are used as thickeners in cosmetic formulations.

The medium molecular mass PEO compounds, up to about 20 000, are hard, brittle waxes. They are used as adhesives, binders, plasticizers, molding compounds, wood impregnants, stiffening agents, and metal-working lubricants. Various PEOs are used in artifact preservation, particularly for items recovered after prolonged water immersion [118], [119]. In particular, copolymers of ethylene oxide and propylene oxide are often used in metal-working fluids and as quenchants, lubricants, and hydraulic fluids.

High molecular mass PEOs are used as textile sizes, as hydrodynamic friction reduction agents, in cosmetics and toiletries, as water-soluble films for seeds, in packaging, in adhesives, and in dentistry. The ability of the high molecular mass polymer to reduce hydrodynamic friction has led to applications in fire fighting and municipal sewage discharge control. The polymer is so effective in reducing the friction of water that it has been banned from use in competitive skiing and boating, where it markedly improved speed when incorporated into waxes and polishes. The association complexes of poly(ethylene oxide) have found use in controlled release of drugs, as adhesives, in artificial kidneys, and microencapsulation.

Poly(propylene oxides) are used as plasticizers, lubricants, solvents, softening agents, antifoaming agents, surface active agents, mold release agents, hydraulic fluid compositions, quenchants, and as intermediates in the production of resins (polyurethanes and alkyds). The largest use of the poly(propylene ox-

ides) and ethylene-oxide- capped PPO polyols is in the production of polyurethane foams and elastomers. The main polyurethanes are those based on toluene-2,4-diisocyanate and 4,4′-diphenylmethane diisocyanate, although light-stable versions based on cycloaliphatic polyisocyanates are made for specialty end uses. The polyurethanes are used as automobile seating, automotive crash pads, furniture cushioning, insulation, bedding, packaging, carpet underlay, molded parts, and many other applications.

The low molecular mass poly(tetramethylene oxide) polyols are used in coatings, to make block copolymers that are used for fabricated parts, and polyurethanes used as elastomeric fibers (spandex fibers). PTMOs have FDA approval for use in polyurethanes and adhesives that come into direct contact with dry foods [120]. The fibers have low hysteresis loss, very good tensile strength, and good tear and abrasion resistance. They are particularly useful for clothing, support garments, knitwear, swimwear, and other similar end uses. No commercial uses are known for high molecular mass PTMO.

7. Economic Aspects [121]

Estimates of the worldwide production of poly(alkylene oxide) polyols for polyurethanes is given in Table 5. Poly(propylene oxide) polyols account for about 95 percent of the polyols produced for polyurethanes, and poly(tetramethylene oxide) polyols account for about 2 percent of the total.

Table 5. Major worldwide production (1990) or consumption of poly(alkylene oxide) polyols [121]

Country	Production, 10^3 t
Production for polyurethane end uses	
Western Europe	931
United States	835
Japan	260
Korea and Taiwan	54
Total	2080
Production for nonpolyurethane end uses	
United States	159
Western Europe	92
Japan	57
Total	308

It is difficult to estimate amounts produced for nonpolyurethane end uses since major companies use the same facilities to produce for both markets. The production for nonpolyurethane end uses is given in Table 5. The majority of the polyol for nonpolyurethane use is for surface active agents (40 %) and for functional fluids and lubricants (31 %). The remainder is used in a wide variety of end uses (see Chap. 6). In the United States, production is about 18.6 % poly(propylene oxides), 31.4 % poly(ethylene oxides), and 50 % ethylene oxide – propylene oxide copolymers. In Western Europe production is about 38 % PPO and PEO, and the remainder copolymers. In Japan production is about evenly divided between PPO, PEO, and copolymers.

The largest manufacturers are:

United States	ARCO, BASF, Dow, E. R. Carpenter, Mobay, Olin, and Union Carbide
Western Europe	ARCO, BASF, Bayer, Dow, Montedipe, and Shell
Japan	Asahi Denka, Asahi Olin, Dow, and Mitsui Toatsu
Republic of Korea	Korea Polyol and Miwon
Taiwan	Chiunglong Petrochemical

Although production of poly(tetramethylene oxide) polyols is included in the production values for polyols as given in Table 5, production of this specialty polyol is delineated by company in Table 6. Polyurethane fibers and elastomers produced from these polyols have tensile properties as good as or better than those of polyesters, together with especially good hydrolytic stability and excellent low hysteresis loss [122].

Table 6. Worldwide production (1990) of poly(tetramethylene oxides) [121]

Company	Production, 10^3 t	Trade name
United States		
Du Pont	30	Terethane
QO Chemicals	11	Polymeg
Wesern Europe		
BASF	4	PolyTHF
Du Pont (Netherlands)	30	Terethane
Japan		
Hodogaya Chemical	3	
Mitsubishi Kasei	4	
Sanyo Chemical	1

Polyoxymethylenes

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated in Plastics, Properties and Testing. Fundamental aspects of polymerization reactions are treated in Polymerization Processes.

1. Introduction

Polyoxymethylenes are thermoplastically processable plastics whose structure is predominantly composed of unbranched chains of oxymethylene units:

$$HO(CH_2O)_nH$$

Polyoxymethylenediol

The term polyacetals is also commonly used for such products. The first systematic investigations of the production and properties of polyoxymethylenes were carried out by STAUDINGER and KERN [1] in the 1920s. Basic properties such as the relatively high softening temperature of ca. 175 °C, high crystallinity, and the ability to form films and fibers were already recognized at that time. However, the insufficient thermal stability of polyoxymethylenes at processing temperatures prevented any practical use of the products.

Following intensive work begun at the end of the 1940s, Du Pont made a breakthrough in 1956 with the production of a high-molecular, thermally stable polyoxymethylene that could be processed thermoplastically [2]. The decisive step consisted of blocking the unstable hemiacetal terminal groups by esterification with acetic anhydride. A production plant with ca. 7000 t/a capacity came on stream in the United States in 1959. The product was introduced on the market under the name Delrin.

$$CH_3-\overset{\overset{O}{\|}}{C}-O(CH_2O)_n\overset{\overset{O}{\|}}{C}-CH_3$$

Polyoxymethylene diacetate (homopolymer)

A few years later Celanese in the United States and Hoechst in Europe succeeded in producing a thermally stable acetal copolymer [3], [4] by copolymerizing trioxane with small amounts of cyclic ethers or cyclic acetals. Compared with homopolymers with blocked terminal groups, the copolymers have the advantage that they are resistant to alkalies, though they have a somewhat lower crystallinity.

$$HO-CH_2CH_2O(CH_2O)_nCH_2CH_2O(CH_2O)_m \cdot \ldots -CH_2O-CH_2CH_2OH$$

Polyoxymethylene produced from trioxane and ethylene oxide (copolymer)

Production of the acetal copolymer Celcon came on stream in 1962 in a 7000 t/a plant at the Celanese plant in Bishop, Texas. The year before Celanese and Hoechst in Germany had already established the joint venture Ticona Polymerwerke, which commenced production of the acetal copolymer Hostaform in 1964. In 1962 Celanese and Daicel formed the joint com-

10.1002/14356007.a21_591

pany Polyplastics in Japan and commenced production of the acetal copolymer Duracon. This was followed in the 1970s by Ultraform (established jointly by BASF and Degussa; product name: Ultraform), the Asahi Chemical Industry Co. (product name: Tenac), and the Mitsubishi Gas Chemical Co. (product name: Iupital). Further plants were built in Poland (product name: Tarnoform) and the former Soviet Union. In the 1980s and early 1990s new plants were constructed mostly in Asia (Korea Engineering Plastics: Kepital; Lucky-Goldstar: Lucel; Taiwan Engineering Plastics).

Polyoxymethylenes are now widely used in areas that were for a long time the preserve of metals. Their low weight and economic processing together with an advantageous combination of mechanical, thermal, electrical, and chemical properties have led to a wide range of applications.

About one third of the market for polyoxymethylenes is accounted for by homopolymers, and about two thirds by copolymers. Capacities of ca. 440×10^3 t/a can be compared with a world demand of ca. 390×10^3 t/a for 1990.

Further details of the production, properties, processing, and uses of polyoxymethylenes can be found in [5], [6].

2. Physical and Chemical Properties

Important physical properties of homopolymers are summarized in [7], and those of copolymers in [8], [9]. Some physical data for polyoxymethylene are given in Table 1 and [10], [11]. Computer disks with materials properties can be obtained from the Western European producers (Material Data Bank CAMPUS: Computer Aided Material Preselection by Uniform Standards [21]).

Morphology. Polyoxymethylene crystallizes in a hexagonal structure with the lattice constants a = 474 pm and c = 1739 pm. The polymer chains have a helical conformation with an identity period of 9/5 [22], [23].

The crystalline density is 1.49 g/cm^3 [22], and that of the amorphous state 1.324 g/cm^3 (homopolymer) and 1.320 g/cm^3 (copolymer) [14]. The density of the commercially available partially crystalline polyacetals is 1.42 g/cm^3 and 1.41 g/cm^3 for homopolymers and copolymers, respectively [7], [8], [24].

The crystallinity of polyoxymethylenes varies between 50 % and 80 %, depending on the comonomer content, molecular mass, and sample pretreatment. Crystallinities of 64 – 69 % for homopolymers and 56 – 59 % for copolymers were found for identical thermal histories [14]. The degree of crystallinity can be increased by thermal posttreatment. Considerably higher values for the crystallite melting point and degree of crystallinity have been reported for the as-polymerized virgin polymer [25].

During crystallization from the melt spherulitic superstructures form. The size of the spherulites depends, among others, on the crystallization temperature and number of nucleation centers. The overall crystallization rate and number of spherulites formed can be increased by adding nucleation agents (see Section 3.4).

Mechanical Properties. Polyoxymethylenes exhibit high hardness and rigidity, high toughness down to $-40\,^{\circ}$C, high thermal dimensional stability, low water absorption, good electrical and dielectric properties, good elasticity, favorable slip and wear behavior, and are easy to process. This combination of favorable properties means that polyoxymethylenes are widely used construction materials.

The structural difference between homopolymers and copolymers results in a lower degree of crystallinity of copolymers. As a consequence homopolymers have about 10 – 12 % higher hardness, rigidity, and strength [5]. However, copolymers possess advantages with regard to thermal and chemical stability.

Standardized test methods are used to determine the physical properties. Since polyoxymethylenes are generally processed by injection molding, the mechanical properties are usually measured on injection-molded test specimens. Slight differences in test specimen production and mechanical testing can result in changes in the measured values. For this reason it is only possible to a limited extent to make an absolute comparison of the property values given in the manufacturers' product brochures [7–9]. Further details are given in [11].

Table 1. Physical properties of polyoxymethylene

Property	Value	Reference
Activation energy of polymerization, kJ/mol		
of cationic polymerization of trioxane in dichloroethane	79.5	[12]
in the solid state	36	[12]
Ceiling temperature, °C		
polymerization of formaldehyde (gas) → polyoxymethylene (solid) at 1 bar	116 – 137	[10]
Coefficient of linear thermal expansion, k^{-1} (ASTM D 696)		
copolymer	0.85×10^{-4}	[13]
homopolymer	0.81×10^{-4}	[13]
Crystallinity, %		
Delrin 550, 20 °C, from density data	68.7	[14]
Hostaform C 9020, 20 °C, from density data	58.7	[14]
Density, g/cm^3		
homopolymer, Delrin 550, 20 °C	1.435	[14]

The suitability of a structural component for a given purpose depends not only on the mechanical properties of the selected raw material, but to a large extent on its structural form and shape [26], [27]. In addition there are influences resulting from the production and environmental conditions, as well as time, temperature, and stress level.

Thermal Properties. The thermal properties of polyoxymethylenes essentially depend on the crystallinity and chemical structure, which are also responsible for differences in the thermal behavior of homopolymers and copolymers.

Homopolymers have higher crystallite melting points (175 °C) than copolymers (164 – 167 °C). Further information on structural changes with temperature are obtained from the torsion vibration test (DIN 53 445), from the temperature function of the mechanical shear modulus G', and the mechanical loss factor d. The transition region (relaxation region) at – 60 °C represents an important embrittlement limit under impact conditions. A second relaxation region exists at 0 °C. A third, subsidiary maximum above 100 °C is attributed to molecular motion in the crystalline regions [11] and is important for the thermal dimensional stability.

The continuous use temperatures are, depending on the type of stress, about 90 – 110 °C [11] and 80 – 100 °C [28]. According to Underwriters Laboratory, Hostaform is permitted for use up to 80 – 105 °C [8]. Experience shows that short-term thermal loading (several hours) up to 140 °C is permissible [28].

The continuous use temperature is largely determined by thermal aging processes, which generally involve thermal-oxidative damage at high temperature. Thermal-oxidative decomposition and decomposition caused by acidic degradation products can be suppressed by adding oxidation stabilizers and costabilizers (see Section 3.4 and [29]).

Thermal stability and continuous use temperatures are, however, not accurately definable material-specific properties and must always be considered in the context of the relevant application.

Temperatures of 190 – 210 °C are generally recommended for processing polyoxymethylenes. Higher temperatures can be used with short-er residence times (e.g., up to 230 °C for copolymers) [6], [8].

The specific heat of copolymers is 1.47 kJ kg^{-1} K^{-1}, and the thermal conductivity is 0.31 W m^{-1} K^{-1} (at 20 °C) [8]. Further thermal data are given in Table 1 and [10], [11].

Chemical Stability. Owing to their high degree of crystallinity, polyoxymethylenes exhibit good resistance to numerous chemicals. Copolymers are also resistant to strong alkalies. Polyoxymethylenes are not resistant to strongly acidic and oxidizing substances.

Only hexafluoroisopropanol and hexafluoroacetone sesquihydrate are suitable as solvents at room temperature. Most other solvents only dissolve polyoxymethylenes above the melting point; these include polar substances such as benzyl alcohol, dimethylformamide, γ-butyrolactone, and phenol [30].

Various investigations on the stability towards numerous chemicals have been published, for example [8], [31], [32].

Conventional organic solvents such as alcohols, esters, ethers, ketones, aliphatic and aromatic hydrocarbons, as well as perhalohydrocarbons do not attack polyoxymethylenes at room temperature even under continuous contact. The mechanical properties are only slightly affected, and the degree of swelling is small.

The good resistance to all common fuels (regular, premium, also fuels containing 15 – 20 % methanol, diesel), as well as to oils and greases, coolants, and brake fluids means that polyoxymethylenes are widely used as construction materials in the automotive sector [8], [33].

Polyoxymethylenes swell only very slightly in contact with water; the water absorption is 0.6 % at 20 °C, and 1.6 % at 100 °C [8]. Copolymers in particular are extremely stable at high temperatures. For example, the tensile strength decreases by only 25 % after two years in boiling water. The copolymers are therefore widely used in washing machines and dishwashers, as well as in water boilers. Alkaline detergents and rinsing agents do not affect the stability of the copolymers. Polyoxymethylenes are generally not subject to stress- cracking.

As regards use in the sanitary sector, varying chlorine contents in tap water, as well as temperature and pressure fluctuations mean that the

suitability must be individually assessed in each case.

UV and Weather Resistance. Polyoxymethylenes can be protected to a certain extent against UV radiation by the use of additives. Suitable UV absorbers include those based on benzophenone or benzotriazole derivatives. In practice, they are combined with HALS stabilizers, which gives a synergistic effect. A further improvement can be achieved by adding carbon black or pigments such as titanium dioxide (see Section 3.4).

Weathering results in a loss of surface gloss, followed by so-called chalking, caused by a layer of degraded, low molecular mass polyoxymethylene. This layer protects deeper-lying layers, so that the reduction in the mechanical properties is greater at the start of weathering, but then decreases. The damage to thin-walled parts is thus greater than to thick-walled parts. The behavior of non-light-stabilized copolymers under natural and artificial weathering is described in [34]. Investigations of the mechanism are given in [35–38].

Various tests are used to evaluate the UV and weathering resistance. Artificial irradiation in the Xenotest and in the Fade-O-Meter produces similar results to natural weathering [37]. Weathering in the Florida test can, depending on the intended use, be performed in the open air or behind window glass. It is not possible to interconvert the various results.

Polyoxymethylenes are only moderately stable to γ-radiation. Medical equipment can be sterilized by using conventional radiation doses of 2.5×10^4 J/kg [8]. The deterioration in the mechanical properties increases with increasing radiation dose [39].

Permeability. Polyoxymethylenes are only very slightly permeable to many gases and solvents. In particular, the very low permeability to propane; butane; aliphatic, aromatic, and halogenated hydrocarbons; alcohols; and esters should be emphasized. The permeability to hydrogen, CO_2, water, and methanol [20], [33], [40] is higher. A comparison with other plastics is given in [11].

Numerous uses have accordingly been found for polyoxymethylenes; for example, cigarette lighters, aerosol containers, and automotive parts in contact with fuels.

Fire Behavior. Polyoxymethylenes burn slowly with a pale blue flame, forming droplets. The external ignition temperature is 350 °C, and the self-ignition temperature is 360 °C.

According to Underwriters Laboratories polyoxymethylenes are classified in Class HB (UL Safety Standard 94). According to the U.S. Federal Motor Vehicle Safety Standard FMVSS 302 and DIN 75 200, the combustion rate does not reach the maximum permitted combustion rate of polyoxymethylenes at wall thicknesses of ≥ 1 mm, and accordingly use in automobiles is permitted. Further information on flammability can be found in [9].

A formulation with the classification V – O is not known.

Optical Properties. Polyoxymethylene moldings are translucent to opaque-white, depending on the thickness. The light transmission of 2 mm thick injection-molded plates is 50 %. The refractive index n_D^{20} is 1.48. The gloss depends mainly on the surface quality of the mold.

Electrical Properties. Polyoxymethylenes have good electrical insulation properties and a favorable dielectric behavior. This, together with the good mechanical properties, means that polyoxymethylenes are useful materials in electrical engineering.

The specific resistivity is $> 10^{15}\,\Omega\cdot$cm, and the surface resistance is $> 10^{13}\,\Omega$. The relative dielectric constant ε_r is 3.6 – 4.0. Since the loss factor tan δ is low, high-frequency heating and high-frequency welding are not possible [8].

The dielectric strength describes the behavior under short-acting stress produced by high voltages. Values of 600 – 700 kV/cm have been measured for polyoxymethylene sheets [8].

Polyoxymethylenes generally do not accumulate static charge. Antistatic and electrically conducting grades have been developed for specialty uses (e.g., Hostaform C 32 021 AST and Hostaform C 9021 ELS [8]).

3. Production

3.1. Polymerization of Formaldehyde and Trioxane

The polymerization of formaldehyde and trioxane proceeds according to an ionic mechanism. Whereas formaldehyde can be polymerized anionically as well as cationically, trioxane, being a cyclic acetal, can be polymerized only under cationic conditions. Polymerization can be performed in the gas phase, liquid phase, in dispersion, and in solution. Trioxane also polymerizes in the solid state.

In practice homopolymers are produced by anionic polymerization of formaldehyde, while copolymers are mainly produced by cationic copolymerization of trioxane with cyclic ethers or cyclic acetals. Processes for producing copolymers that use formaldehyde as starting material have also been described [41].

A review of the historical development of polyoxymethylenes is given in [42–44]. Comprehensive summaries of the homopolymerization and copolymerization of trioxane can be found in [45], [46].

For information on the most important process steps in the production of homopolymers and copolymers, together with numerous literature and patent references, see [47].

3.2. Homopolymers

Terminal-group-stabilized homopolymers of formaldehyde with adequate thermal stability were first developed by Du Pont [2], [47–49].

The production process can be divided into the following steps:

1) Oxidation of methanol to formaldehyde
2) Purification of formaldehyde
3) Polymerization
4) Terminal group capping
5) Homogenization of the polymer in the melt; addition of auxiliaries

The production of formaldehyde from methanol is described in → Formaldehyde, Chap. 4. The formox or silver catalyst process is usually used; see also [50].

High-purity formaldehyde is required for the polymerization step. Purification on an industrial scale can be performed, for example, by absorbing the reaction gases from the formox or silver catalyst process in cyclohexanol [51], [52]. Cyclohexanol hemiformal is formed from formaldehyde and cyclohexanol; water and other impurities are then removed by vacuum distillation. Vacuum distillation is followed by thermal cracking. The resultant formaldehyde gas can then be passed after further purification (e.g., removal of reactive impurities by partial polymerization [53], [54]) to the actual polymerization process [48]. Amines [54]; alkoxides [55]; ammonium and sulfonium salts [56]; metal carbonyls [57]; and phosphines, arsines, and stibines [58] are suitable initiators for anionic polymerization.

The high heat of polymerization (ca. 60 kJ/mol [10]) must be removed. Suspension polymerization has proved convenient in practice. Aliphatic or cycloaliphatic hydrocarbons are suitable suspension agents, for which the same purity requirements apply as for the monomer.

The purified formaldehyde is added to a reaction vessel containing the suspension agent (e.g., cyclohexane) and initiator (e.g., tri-*n*-butylamine). The polymerization can be carried out at room temperature and under normal or reduced pressure. The polymer is formed as a fine suspension.

In the next step the thermally unstable hemiacetal terminal groups of the polymer are converted into alkyl or acyl groups. In particular esterification with acetic anhydride has become industrially important [2]. The reaction can, for example, be carried out in the presence of small amounts of sodium acetate as catalyst in boiling acetic anhydride.

This conversion stage is followed by several purification steps. Finally, the polymer powder is melted in extruders with the addition of antioxidants, co-stabilizers, and other additives, and converted into granules.

3.3. Copolymers

The copolymer production process is divided into the following steps:

1) Oxidation of methanol to formaldehyde

2) Trimerization of formaldehyde to trioxane
3) Purification of trioxane
4) Copolymerization of trioxane with cyclic ethers or cyclic acetals
5) Removal of unstable terminal groups
6) Homogenization of the polymers in the melt; addition of auxiliaries

The production of formaldehyde and trioxane is described in → Formaldehyde, Chap. 4., → Formaldehyde, Chap. 6.2. The trioxane must satisfy strict purity requirements for the subsequent cationic polymerization. Compounds having a chain-transfer action such as water, methanol, methyl formate, formic acid, and methylal must be removed as far as possible. Chain-transfer reactions lower the attainable molecular mass [59]:

$$\sim\sim O-CH_2-O-CH_2^+ + H_2O \longrightarrow \sim\sim O-CH_2-O-CH_2-OH + H^+$$

Growing chain end Unstable chain end

The proton then initiates a new chain. The final purification to polymerization grade trioxane is generally carried out by crystallization [60],[61] or distillation.

A large number of compounds may be used as initiators for the cationic polymerization. Important catalysts include

1) Lewis acids, such as BF_3, and their complexes (e.g., $BF_3 \cdot Bu_2O$) [62]
2) Protic acids such as perchloric acid, perfluoroalkanesulfonic acids, as well as their alkyl esters or anhydrides [63]
3) Heteropoly acids such as tungstophosphoric acid [64]
4) Carbenium salts such as triphenylmethyl hexafluoroarsenate [65], oxocarbenium salts, onium compounds, and metal chelates

The desired molecular mass is regulated by chain-transfer agents such as methylal and butylal [66].

Suitable comonomers include cyclic ethers and cyclic acetals. In particular, ethylene oxide [67], 1,3-dioxolane, diethylene glycol formal [68], and 1,4-butanediol formal are used. The comonomers are generally used in amounts of 2 – 5 wt %.

The polymerization of trioxane can be performed in bulk, solution [69], or suspension [70]. For solution and suspension polymerization the same solvents may be used as for formaldehyde polymerization. Bulk polymerization is the preferred method in practice.

Bulk polymerization is generally carried out in self- cleaning kneaders or double-screw reactors [71], [72] at 70 – 115 °C. Polymerization is complete within a few minutes, and a very hard, crystalline polymer is formed. The heat of polymerization, ca. 23 kJ/mol [73], must be removed to prevent monomer losses due to evaporation of trioxane.

Other polymerization processes have been reported, including solid-state copolymerization of trioxane/1,3-dioxolane [74], homogeneous-phase polymerization [75], polymerization in an open vessel [76], and a drum process [77].

The copolymers contain the comonomer units in statistically distributed form. Only part of the terminal groups is formed from comonomer units. The unstable hemiacetal and formate terminal groups must be removed by heat treatment. In practice, both solution [78], [79] and melt [80], [81] processes have proved suitable. Solution processes are generally carried out at 150 – 200 °C, and melt processes at 170 – 250 °C. Amines or phosphines, for example, are added to deactivate the acid catalysts. The objective of all the processes is to completely remove unstable terminal groups and residual monomers from the polymer.

The solution processes are very efficient but have the disadvantage of high energy consumption. After thermal treatment, the product is precipitated in powder form by lowering the temperature. The adhering residual solvent is removed mechanically and thermally. The dry powder, together with stabilizers and other, optional additives, is melted and homogenized in extruders and processed into granules.

Although the melt processes do not achieve the efficiency of the solution processes, they require less energy. After addition of stabilizers the melt can be processed directly into granules.

A large number of patent applications have been filed by various companies for the polymerization as well as the work-up process, e.g., [82–90]. The Asahi process, in which formaldehyde is prepared from methylal instead of by direct oxidation of methanol [91] is described in [92].

The mechanical properties are measured by the conventional methods used for polymer materials. Test methods and values can be obtained from the brochures of the raw material manufacturers [7], [8], [9]. See also Table 1 as well as [11] and Chapter 5.

3.4. Additives

Stabilizers. Polyoxymethylenes can be decomposed by the action of high temperatures, oxygen, shear forces, and/or acidic substances. These influences are especially important in the processing of the products in the melt. Further influences may also occur when using the finished parts.

In the case of terminal-group-stabilized polyoxymethylenes, decomposition begins by chain scission. Above the melting point, chain scission is followed by depolymerization with elimination of formaldehyde. For copolymers, this involves elimination of formaldehyde units until the next stabilizing comonomer unit is reached. In the case of homopolymers complete decomposition of the polymer chain occurs. Formic acid, which can initiate an acidolytic chain scission, is formed as byproduct of the decomposition by oxidation of formaldehyde or by disproportionation. Acidic catalyst residues can also produce chain scission [93], [94]; for further details, see [95].

Only multicomponent systems are used to stabilize polyoxymethylenes. Phenolic compounds in particular have proved suitable against thermal-oxidative decomposition (antioxidants). Alkaline-earth metal salts and nitrogen-containing compounds, among others, are used to prevent acidolytic decomposition (acid trapping agents). Formaldehyde trapping agents can be used to further improve the stability.

The following compounds are used as antioxidants:

1) 4,4′-Butylidenebis(6-*tert*-butyl-3-methylphenol) [96]
2) Triethylene glycol bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionate] [97]
3) 1,6-Hexamethylene bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionate] [98]
4) 2,2′-Methylenebis(4-methyl-6-*tert*-butylphenol) [99]

The following compounds, among others, are used as acid trapping agents:

1) Dicyanodiamide, melamine [100]
2) Calcium carbonate, stearate, or montanate [101]
3) Polycondensates of formaldehyde, isophthalamide and 2-imidazolidinone [102]
4) Polyamides [103]
5) Triazine derivatives [104]

The nitrogen-containing compounds also act as formaldehyde trapping agents. Other formaldehyde trapping agents include polyhydroxy compounds such as poly(vinyl alcohol) [105].

The aforementioned classes of stabilizers can be combined in numerous ways. Optimum utilization of the possible synergistic effects can be achieved only by carefully matching all the components.

Damage caused to polyoxymethylenes by UV radiation and weathering is described in Chapter 2. The addition of organic light stabilizers and special pigments has proved useful in improving the resistance to UV radiation and weathering.

Compounds from the following classes are used as light stabilizers [106–108]: benzotriazoles, benzophenones, benzoates, oxanilides, and sterically hindered amines (HALS stabilizers). Synergistic effects can also be achieved here by suitable combinations of stabilizers of different classes of compound, in particular combination with HALS stabilizers. Titanium dioxide and, in particular, carbon black are suitable pigments.

All the above-mentioned stabilizers and pigments are incorporated into the polymer melt.

Nucleation Agents. The following are suitable as nucleation agents for polyoxymethylenes:

1) Branched or cross-linked polyoxymethylenes [109]
2) Trioxane block copolymers [110]
3) Special melamine – formaldehyde resins [104], [111]
4) Boron nitride [112]
5) Talcum [113]
6) Antimony trioxide [114]

Even in amounts of less than 1 wt % these compounds accelerate crystallization of the melt. Nucleated polyoxymethylene molding compounds often allow earlier removal from the mold, and thus a reduction of the cycle time, in injection molding processing. The resulting spherulite structure is finer and more uniform, which results in increased strength and toughness [11], [115].

Release Agents. The addition of release agents may be advantageous for the production of complicated molded parts. Suitable additives include, for example, polyethylene waxes, montanate esters and salts, *N,N′*(bis-stearoyl)ethylenediamine, fatty alcohols, and fatty acid salts.

3.5. Impact-Resistant Types

Polyoxymethylenes are materials that already have a high basic toughness, without the need for further modification. However, the toughness can be improved further by impact resistance modification with elastomers.

The first commercial impact-resistance-modified polyoxymethylenes were introduced in 1982, and in the meantime several manufacturers have developed products of this type. The various products differ according to their flow behavior and degree of impact resistance modification. Compared with the unmodified products the impact-resistant types have slightly reduced rigidity, hardness, and thermal dimensional stability, though this is compensated by a substantially higher energy absorption under impact and tensile stress.

The conventional types are based on blends of polyoxymethylene and thermoplastic polyurethane elastomers [116–120]. Products in which cross-linked rubbers having a particularly low glass transition temperature and a fixed particle size are used for the impact strength modification have been developed more recently [121].

Impact-resistant polyoxymethylenes are produced by mixing the components in the melt, using single-screw or double-screw extruders. Processing into moldings is performed by the same methods as are used for unmodified polyoxymethylenes. Whereas polyurethane-modified products have, depending on the extrusion and processing conditions, a variable morphology of the impact-resistant component (size, shape, and distribution of the particles), the rubber-modified products have a uniform particle morphology. In addition to the particularly high low-temperature impact resistance, the new products have further advantages, including the extremely good weld line strength and the absolute absence of delamination during processing [122].

4. Economic Aspects

Table 2 lists producers of polyoxymethylenes, together with their capacities and trade names [123].

A demand for polyoxymethylenes of about 390×10^3 t/a can be compared with a nominal capacity of ca. 440×10^3 t/a for 1990. Homopolymers accounted for about 30 % of the total market.

5. Quality Specifications and Analysis

Residual monomer content, molecular mass, thermal stability, and mechanical properties are important quality criteria for polyoxymethylenes. For the copolymers there is in addition the comonomer content.

The so-called lutidine or acetylacetone method [124], which is specified by the BGA to evaluate the formaldehyde content of plastic molded parts that come into contact with foodstuffs [125], [126], is generally used to measure the content of extractable formaldehyde in granules or in molded parts. Formaldehyde can also be determined with chromotropic acid or by titration with sodium sulfite solution. The tests are normally performed on aqueous extracts of the materials.

The molecular mass is monitored in practice via the melt viscosity (melt flow index, MFI). Various $\eta - M$ relationships are given in the literature for molecular mass determination by means of the solution viscosity. Usual solvents are dimethylformamide and hexafluoroacetone – water mixtures [127], [128].

The weight loss that occurs in the melt at a specific temperature over a certain time and in

Table 2. Producers, capacities, and trade names for polyoxymethylenes in 1990

Region	Producer	Capacity, 10^3 t/a	Product type	Trade name
Western Europe	Hoechst (Ticona)	50	copolymer	Hostaform
	BASF (Ultraform)	30	copolymer	Ultraform
	Du Pont	55	homopolymer	Delrin

Former Soviet Union		10	copolymer	
Poland		10	copolymer	
China		10	copolymer	

a defined atmosphere (air, nitrogen) can be used to evaluate the thermal stability [129], [130].

NMR spectroscopy is suitable for monitoring the comonomer content in the end product [131]. When the comonomer is ethylene oxide, the frequency of occurrence of mono-, di-, and triethylene glycol units can also be determined with this method.

IR spectroscopic methods have been described for the determination of terminal groups in acylated homopolymers [132], [133].

Conventional analytical techniques such as UV, IR, NMR, and ashing, optionally in combination with suitable separation methods, can be used for the qualitative and quantitative determination of additives, fillers, and reinforcement agents in the end product.

6. Product Range and Processing

Polyoxymethylenes are produced in various degrees of polymerization. The individual types differ as regards their flow behavior (melt index) and in the choice and concentration of additives and colored pigments. Reinforced types, types with improved slide and wear behavior and impact resistance, and products with anti-UV additives are also available [7–9]. The usual supply form is granules of about 3 mm grain size.

Polyoxymethylenes can be processed with all conventional machinery for thermoplastics, such as injection molding machines, extruders, injection and extrusion blow units, as well as by compression. Temperatures between 190 °C and 210 °C are generally recommended for processing. The temperature in the melt should not exceed ca. 230 °C [8], [9].

Posttreatment of injection moldings is generally not necessary. Machining, in which parts are fashioned from the bulk plastic (semifinished product), has, however, become important. Machining is economically practicable up to medium-size production runs, particularly if computer numerical control techniques are used.

In the "outsert" technique a wide range of polyoxymethylene functional components are bonded to a metal blank in a single step in an injection molding process [134]. Such components include guiding and sliding el-ements, bearings, axles, columns, snap connections, and spring components. They are used, for example, in compact disc drives and in cassette and video recorders.

Further information on processing is given in [5], [6], [11].

7. Uses

Polyoxymethylenes have a balanced combination of favorable properties for technical use, such as hardness, rigidity, toughness, spring elasticity, and resistance to fuels. The range of uses has been broadened further by a large number of modified special grades. Polyoxymethy-

lenes are used in almost all sectors of industry and technology. The main areas of polyoxymethylene consumption in Western Europe are the automotive sector (39 %), domestic, household and office equipment (14.7 %), and in electrical engineering and the electronics industry (10.8 %) [122]. Further uses include mechanical engineering, machine construction, sanitary uses, medical technology, toys, and cosmetics.

Utility articles and parts fabricated from polyacetals vary widely as regards their range of application and are accordingly so numerous that it is only possible to list the most important uses. Some examples of applications are as follows [5], [6]:

Automotive sector: parts for gasoline pumps, gasoline gauges, carburettor floats, brake boosters, chain wheels, clips, tank closures, water separators, lock housings, fan blades, and gas bubble separators.

Electrical industry: gearwheels, bearings, springs, radial cams, lifters, tappets, axles, pinions, gears, transmissions, worm gears, computer keyboards, water boilers, and parts for leakage current protection circuits.

Mechanical engineering: valves, pistons, sliding bearings, and ball-type nipple cages.

Sanitary sector: handsprays, fittings, control flaps for WC flush units, and functional parts in water and gas meters.

8. Recycling

On account of the high commercial value of polyoxymethylenes a functioning material recycling system for polyoxymethylenes already exists. Many plastics processors use material residues directly themselves and contribute substantially by means of this internal recycling process to reduce waste. Polyoxymethylene waste is also processed by compounders into regranulate. This regranulate is, however, of poorer quality than the original material.

Hoechst has developed a closed-loop recycling process, in which polyoxymethylene waste is decomposed into the monomer starting materials. The decomposition products are purified and repolymerized [135]. The cycle can be repeated as often as desired without affecting the quality.

9. Toxicology and Occupational Health

Polyoxymethylenes are odorless and tasteless. Feeding tests have not produced any positive clinical results. Skin compatibility investigations showed that polyoxymethylene does not irritate intact skin [40], [136].

There are no objections to the use of polyoxymethylene moldings that come into contact with foods, as long as the regulations of the licensing authorities (BGA [125], FDA [137], [138]) are satisfied and the parts are suitable for the intended use. The regulations cover the nature and amount of monomers, comonomers, catalysts, deactivators, regulators, stabilizers, lubricants, and fillers, and specified contents of fluorine, boron, zinc, and amines must not be exceeded. A maximum permissible upper limit is specified for formaldehyde traces that can be extracted from finished parts.

The maximum permitted workplace concentration for formaldehyde should also be observed when processing polyoxymethylenes. In Germany the MAK is 0.5 ppm (0.6 mg/m^3), and in the United States the TLV-TWA is 1.0 ppm (1.2 mg/m^3) [as of 1991]. These limits may be exceeded for a short period only if certain preconditions are satisfied. For further details see → Formaldehyde, Chap. 10..

Poly(Phenylene Ethers) → Poly(Phenylene Oxides)

Poly(Phenylene Oxides)

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated inPlastics, Properties and Testing. Fundamental aspects of polymerization reactions are treated in Polymerization Processes

1. Introduction

Poly(phenylene oxides) [*9041-80-9*], also known as poly(phenylene ethers) or poly-oxyphenylenes, refer to a class of polymers made by the oxidative polymerization of substituted phenols. A large variety of polymers have been investigated based on differently substituted phenols (Table 1). However, only poly(2,6-dimethyl-1,4-phenylene ether) [*25134-01-4*] (PPE) has significant utility, albeit in blends with other polymers such as polystyrene or polyamide:

PPE

History. The discovery of poly(2,6-dimethyl-1,4-phenylene ether) in 1956 by Hay (General Electric) [1] marked the introduction of the catalyzed oxidative coupling of phenols as a means of obtaining engineering resins. This poly(phenylene oxide) made from 2,6-dimethylphenol can be regarded as amorphous for all practical purposes [2], and possesses a high glass transition temperature (T_g 211 °C) in addition to an extremely high melt viscosity, which requires high processing temperatures that lead to side reactions [3], [4]. Only through the exceptional miscibility of PPE and polystyrene (PS) [5] could acceptable processing temperatures and melt viscosities be achieved. This development led to the marketing of the first commercial poly(phenylene oxide) in 1964 – Noryl, a blend of PPE and impact modified PS (HIPS). These PPE – HIPS blends are unique because their ultimate use temperature can be easily adapted to application requirements by adjustment of the PPE – HIPS ratio. GE Plastics was the sole supplier of modified PPE until 1983 when its original patents expired; other companies (e.g., BASF with Ultranyl and Hüls with Vestoran) have now introduced their own PPE grades. A blend of HIPS and a PPE copolymer with a similar property profile to poly(2,6-dimethyl-1,4-phenylene ether) was introduced in the early 1970s under the trade name Prevex (Borg – Warner and Mitsubishi Chemicals):

Over 200 000 t/a of modified PPE are sold worldwide, mainly for applications in the automotive, electronics, and electrical industries.

2. Production

The synthesis of PPE from 2,6-dimethylphenol, using an amine complex of a basic cupric salt as a homogeneous oxidation catalyst, follows a complicated polymerization mechanism which has not been completely resolved [6], [7].

The main byproduct of the polymerization is 3,3′,5,5′-tetramethyldiphenoquinone (TMDPQ):

TMDPQ

The oxidative coupling chemistry is very versatile because different di-*ortho*-substituted phenols can be used for the formation of 2,6-substituted aromatic (co)polyethers (Table 1). However, only PPE is of commercial importance.

Commercial PPE production can be performed batchwise or continuously. Different reactor designs are possible depending upon the choice of the solvent and introduction of oxygen (pure oxygen or air – oxygen mixtures). A gas – liquid reactor is used to avoid low reaction rates associated with diffusion of air into the liquid. Reaction temperatures are typically 20 – 65 °C. At higher temperatures, formation of TMDPQ increases and should be avoided. The solubility and viscosity of the final polymer solution depend on the solvent, temperature, polymer concentration, and its molecular mass. Commercial PPE is produced with a weight-average molecular mass of 32 000 – 40 000.

The following stages can be discerned (Fig. 1):

Figure 1. Commercial production of PPE

1) Preparation of the catalyst solution
2) Preparation of reaction mixture
3) Polymerization using oxygen or oxygen – air mixtures
4) Termination of polymerization at a certain degree of polymerization
5) Removal of copper catalysts from the reaction mixture using a copper complex as complexing agent and liquid – liquid extraction
6) Concentration of PPE solution
7) Precipitation of PPE in a nonsolvent
8) Repeated washing and drying (purification of resin)

3. PPE Blends

3.1. PPE – PS Blends

A processible, commercially attractive material is obtained by blending PPE with PS (Fig. 2). The unique, complete miscibility of this blend presumably results from interaction between the π-electron donor PS and the electron-deficient methyl groups of PPE [8]. The T_g of the blend can be varied almost linearly between 100 and 215 °C over the complete composition range of PS and PPE (Fig. 3). Table 2 shows some important properties of PPE – HIPS blends.

Figure 2. Blending criteria for PPE – PS

Figure 3. Thermal properties of PPE – HIPS blends
a) Glass transition temperature, T_g; b) Vicat B softening temperature; c) Heat distortion temperature

Commercial blends such as Noryl (GE Plastics) or Luranyl (BASF) make use of PS impact-modified with polybutadiene (high-impact polystyrene, HIPS). Impact modification of these blends comprising a ductile resin (PPE) and a brittle one (PS) poses an interesting problem because the two components require different rubber particle sizes for optimal impact modification (Fig. 4). Diluting HIPS with PPE yields a more ductile matrix in which smaller rubber particles (diameter 0.5 – 2 µm) are more effective in impact modification than the larger particles (2 – 12 µm) [9], [10]. The larger particles

are more effective at higher HIPS levels [11]. Processing temperatures of PPE-rich compositions above 80 °C cause additional cross-linking of the polybutadiene rubber phase, rendering it less effective.

Figure 4. Notched impact strength of PPE – HIPS blends impact-modified with polybutadiene rubber (10 wt %, content in HIPS)
a) 0.5 – 2 µm polybutadiene rubber; b) 2 – 12 µm polybutadiene rubber

PPE – HIPS grades offer relatively constant mechanical properties over a wide temperature range. Ultimate use temperatures of PPE – HIPS blends, as estimated from UL temperature ratings, are between 90 and 100 °C (see Table 2).

The very low water absorption of PPE –HIPS blends and their favorable mechanical properties contribute to a high dimensional stability under load, the most important property of engineering thermoplastics.

Polymer miscibility is not restricted to the PPE – HIPS system, but also holds for combinations of other substituted poly(1,4-phenylene oxides) (see Table 1) with styrene homopolymers such as poly(α-methylstyrene), poly(4-methylstyrene), and styrene copolymers in which the comonomer content is limited to maintain full miscibility with PPE.

Adjustment of the maximum use temperature offered by blend technology also applies to the UL-94 flammability ratings of the PPE – HIPS grades (Fig. 5). For a description of UL-94 ratings, see → Flame Retardants, Chap. 3. PPE is intrinsically flame extinguishing as exemplified by its high limiting oxygen index (LOI) value of 29. HIPS, on the other hand, has a LOI of 17 and burns easily and completely [12]. Blending these two miscible polymers provides an intermediate flammability behavior which can be further improved by adding triaryl phosphates to produce flame-retardant PPE – HIPS grades that meet required industrial specifications without utilizing halogen-containing compounds [13]. Since the organic phosphate also functions as a plasticizer, a higher percentage of PPE is required to maintain a given heat distortion temperature (HDT) (Fig. 3). This leads to a well-balanced relation between flame retardancy behavior, composition, and HDT. The flame-retardant PPE – HIPS grades also have excellent melt processibility.

Figure 5. UL-94 flammability ratings of PPE – HIPS blends with different triaryl phosphate contents

Enhanced flame retardancy, however, decreases the comparative tracking index (CTI), a criterion used for applications in the electrical and electronics industry (→ Insulation, Electric, Chap. 2.1.). This problem can be solved by the addition of inorganic fillers (e.g., glass fibers) and has led to the development of special grades.

PPE – HIPS blends are, like most polymers, excellent electrical insulators. The dielectric loss factor, a measure for the loss of electrical energy through heat buildup, is < 0.002 in the range 1 – 16 MHz over a wide temperature span [14]. For other electrical properties of poly(phenylene oxides), see → Insulation, Electric.

Chemical resistance of PPE – HIPS blends is summarized in Table 3. Temperature, strain level, contact time, and the chemical nature of the contact liquid strongly affect the related environmental stress cracking phenomena. PPE – HIPS blends have an intrinsically high resistance

against hydrolysis under acidic and basic conditions.

Table 3. Chemical resistance of PPE – HIPS (Noryl) and PA – PPE (Noryl GTX) blends

3.2. PA – PPE Blends

PPE can also be used as an organic filler in semicrystalline matrices such as polyamides (PA 66 or PA 6). PA – PPE blends have been specifically developed for on-line painted exterior automotive parts with excellent ("class A") surface quality.

The favorable processibility properties, chemical resistance, and impact resistance of PA are combined with the high-temperature performance of PPE. PA – PPE blends were the first commercial blends of two completely incompatible polymers and are different from the fully miscible PPE – HIPS system. Blends of immiscible polymers are thermodynamically unstableand lack morphological stability, which leads to phase separation and delamination. This can be overcome by the use of compatibilizers (concen-tration usually ≥ 10 wt %), which are frequently A–B block copolymers. The compatibilizers reduce the interfacial tension between the constituent polymers, resulting in greatly improved dispersion of PPE in PA. They also provide strong bonding between the dispersed and the continuous phases (important for mechanical properties), and increase morphological stability by preventing agglomeration of dispersed particles. The latter is important as it allows processing of the blends under practical shear conditions such as exist in injection-molding equipment.

Compatibilization is achieved either by adding PA – PPE block copolymers or by in situ formation of these block copolymers. The latter is achieved by addition of PPE end-capped with functionalized maleic anhydride (Fig. 6 A) or by addition of PS grafted with maleic anhydride (Fig. 6 B). The anhydride groups react with the amine end groups of the PA polymers and form a compatibilizing linear PA – PPE block copolymer (Fig. 6 A) or a grafted PS – PA block copolymer (Fig. 6 B). Figure 7 shows the effect of compatibilization as determined by scanning electron microscopy [15]. Higher concentrations of PA – PPE copolymers reduce the dimensions of the dispersed PPE phase.

Figure 6. Schematic representation of compatibilization of PA – PPE using PPE end-capped with functionalized maleic anhydride (A) or PS grafted with maleic anhydride (B)

PPE is a ductile material which can be impact-modified to form extremely tough blends. The high glass transition temperature of

Figure 7. Effect of compatibilization on PA – PPE morphology as determined by scanning electron microscopy with PA as the continuous phase (courtesy of S. Y. Hobbs, General Electric)
A) No compatibilizer; B) 8 wt % compatibilizer; C) 15 wt % compatibilizer

PPE also increases the strength, rigidity, and dimensional stability of the PA – PPE blends up to the temperature required for automotive lacquering. The blends are usually impact-modified phase selectively with various rubbers located in the PPE or PPE – PS phase dispersed in the PA phase. Two-phase impact modification of the PPE (or PPE – HIPS) and the PA phases is also possible by appropriate selection of the rubbers. The PA – PPE blends can thus easily be adapted to give the ultimate use temperatures and impact levels required for specific lacquering and painting applications of exterior automotive parts (see Fig. 8). Ranges of temperature requirements for various coating techniques are indicated.

Figure 8. Ultimate use temperature plotted against impact strength of commercially available PA – PPE blends (Noryl GTX, GE Plastics), ranges of possible coating techniques are indicated

Table 4 shows important properties of PA – PPE blends. Polyamides are known for their high moisture absorption which reduces their dimensional stability. Addition of PPE to PA lowers the water absorption but, remarkably, PA – PPE blends absorb less moisture than that calculated from their PA volume fraction (Fig. 9). The resulting blend thus has a greater dimensional stability than PA, providing a more constant mechanical property profile with temperature and relative humidity. This dimensional stability can be further enhanced by reinforcing the material with glass fibers. Special grades exist for bumper beams that combine high-temperature paintability with low-temperature impact performance.

Figure 9. Water absorption of PA and PA – PPE at 23 °C and 50 % R.H.

Advantages of PA – PPE blends over PPE – HIPS blends are their better chemical resistance (see Table 3), improved environmental stress cracking resistance, and a higher ultimate use temperature range.

3.3. PPE – Polyolefin Blends

In 1989 GE Plastics introduced a blend series (Noryl Xtra) containing ≥ 90 % PPE. The high melt viscosities of PPE (see Chap. 1) were reduced using plasticizers and olefinic components of proprietary composition as flow promoters. The resins combine good processibility

with high dimensional and temperature stability up to 195 °C as well as an UL-94 V-0 flammability rating. The materials have a high surface gloss and can be used as light reflectors.

Figure 10. PPE – HIPS dashboard (Noryl, GE Plastics)

In addition to excellent intrinsic flame retardancy properties, the special-grade Noryl Xtra LS generates an extremely low amount of smoke during burning because it contains PPE-specific char promoters. This feature is extremely important for its use in electrical insulation applications in enclosed or inaccessible areas (airplanes, ships, public buildings).

4. Processing

Melt viscosities of all PPE – HIPS and PA – PPE grades conform to the processing capabilities of conventional melt-processing equipment (injection molding, extruding etc.). However, PA – PPE blends require a more stringent drying procedure, and care should be taken with PPE – HIPS blends not to exceed the recommended drying time of 4 h at 110 °C, since this leads to loss of impact resistance. Processing temperatures of standard grades are typi-

cally 220 – 270 °C for PPE – HIPS, 280 – 300 °C for PA – PPE, and 320 – 340 °C for PPE – olefin blends. Injection molding and glass-filled grades require slightly higher temperatures.

5. Uses

The most important application areas for PPE blends are in the automotive industry (35 %), in electric and electronic appliances (25 %), office equipment (15 %), and (hot) water distribution and environmental applications (8 %) [13].

Interior Automotive Applications. The development of PPE – HIPS blends marked the break-through of plastics for interior automotive applications. The most significant applications are dashboards of PPE – HIPS (Fig. 10), a development that started in Europe and was followed worldwide. Other applications include radio housings, loudspeakers, and heating and ventilation systems. So called "antisqueak" materials used for handgrips and ventilation grills.

Figure 11. Fenders of 1991 Renault Clio 165 (Noryl GTX, GE Plastics)

Exterior Automotive Applications. The on-line and off-line paintability of PA – PPE blends provided by their high-temperature performance, their "class A" surface with excellent dimensional stability, and good mechanical properties in combination with low-temperature impact resistance makes them suitable for vertical body panels, bumpers, petrol filling caps, wheel trims, grilles, spoilers, electromechanical systems (EMS), and fenders for the 1991 Renault Clio 16 S (Fig. 11). These applications allow for easy styling changes, weight savings, and, most importantly, cost savings. The latter is particularly important for "small" production series of 50 000 vehicles per year.

Electrical and Electronics Industry. Flame-retardant PPE – HIPS grades are used mostly on account of their good processability, good mechanical properties, and flame retardancy behavior without using halogens. Typical applications are housings for electrical equipment (Fig. 12), connectors, switches, and interior parts in laundromats. PA – PPE blends can be used in paintable extrusion and blow molding parts.

Figure 12. PPE – HIPS housing (Noryl, GE Plastics)

Data Processing and Office Equipment Industry. Flame-retardant PPE – HIPS blends or, alternatively, painted structural foams are used for in-house appliances such as computer housings. These materials are provided with a UV-stabilizing system to comply with the most stringent demands for color stability.

The hydrolytic and dimensional stability of PPE – HIPS blends and the reduced stress – crack sensitivity provided by glass fiber reinforcement makes them suitable for applications in water and air purification systems. All blends in applications involving food contact or drinking water are approved by the FDA.

Building and Construction. This industry segment constitutes a new market for PPE blends. The low sales percentages result from the fact that traditional materials are still used in potentially large-volume applications such as insulation systems or solar collectors.

New Developments. A few promising new developments can be mentioned. In situ PPE – PS blends used to make expandable beads give strong foams with a low density (to 0.02 g/cm^3) and a heat distortion temperature above 100 °C, a sterilizable and reusable material (Fig. 13).

Figure 13. Beakers made from PPE – PS expandable beads (Caril, Shell)
Bead size 300 – 500 µm, density 60 g/L, T_g 110 °C

The use of PPE as an organic, highly heat-resistant, flame-retardant filler that does not affect mechanical properties at high filling ratios, as demonstrated for PA – PPE blends, will be applied to other blend systems (Section 3.2). These new blends include a blend of PPE and poly(butylene terephthalate) which has an even lower moisture absorption than PA – PPE blends and thus higher dimensional stability. Blends of chemically modified PPEs will also find increased use, aimed at applications with specific requirements.

1. Polystyrene

1.1. Introduction

Polystyrene (PS) belongs to the group of standard thermoplastics that also includes polyethylene, polypropylene, and poly(vinyl chloride). Because of its special properties, polystyrene can be used in an extremely wide range of applications. The annual consumption worldwide in 2004 was ca. 11.5×10^6 t; thus polystyrene is one of the most quantitatively important chemicals.

Historical Aspects. Styrene [*100-42-4*] (known as styrax) was first isolated in 1831 by Bonastre from the resin of the amber tree. In 1839 E. Simon, who also first described the polymer, gave the monomer its name. He observed that styrene was slowly converted into a viscous solution on standing. Around 1925 the development of an industrial production process for polystyrene began; this work achieved success in the plants of the IG Farbenindustrie in Germany in 1930 [1]. In the United States polystyrene was first produced on a commercial scale in 1938 by the Dow Chemical Company.

Polystyrene and Impact-Resistant Polystyrene. Chapter 1 deals with the clear polystyrene molding materials [*9003-53-6*] and rubber modified polystyrene [*9003-55-8*], also known as styrene – butadiene molding material.

Polystyrene molding materials are hard, transparent materials with a high gloss. They are most commonly described as general-purpose polystyrene (GPPS) but terms such as standard polystyrene, normal polystyrene, clear polystyrene, crystal polystyrene, or styrene homopolymer are also in use. In this article the definition polystyrene molding material (PS) is used according to ISO 1622–2.

Below 100 °C PS molding materials solidify to give a glasslike material with adequate mechanical strength, good dielectric properties, and resistance toward a large number of chemicals for many areas of application.

Above its softening point clear polystyrene occurs as a melt which can be readily processed by techniques such as injection molding or extrusion. Small quantities of lubricants can be used internally or externally as processing aids. The addition of antistatic agents, UV stabilizers, glass fibers, or colorants is also common.

The mechanical properties of the relatively brittle PS molding materials can be considerably improved by adding rubbers, generally polybutadiene [*106-99-0*]. Styrene – butadiene molding materials are generally referred to as high-impact polystyrene (HIPS), this term is used here. They are also known as toughened PS or rubber-modified PS; ISO 2897–2 defines them as impact-resistant polystyrene (IPS).

Early production processes for HIPS were based on mixing PS molding materials with a rubber component. Polymerization of a styrene – polybutadiene solution is, however, much more effective. A two-phase system is formed due to the immiscibility of polystyrene and polybutadiene. Polystyrene forms the continuous phase (matrix) and polybutadiene the disperse phase. The globular rubber particles contain small inclusions of polystyrene (Fig. 1).

The additives commonly used with PS molding materials can also be employed in HIPS. Paraffinic white oil is commonly used as lubricant, zinc stearate as mold release agent. Antioxidants are used for rubber stabilization. Flame retardants, antistatic agents, and other additives are added for special applications.

Figure 1. Electron micrograph of HIPS molding material The dispersed rubber particles (dark as a result of OsO_4 treatment) are embedded in the polystyrene matrix (lighter regions). The rubber particles contain lighter polystyrene inclusions

Figure 2. Electron micrograph of a transparent IPS molding material (SBC, contrasting as in Fig. 1). The size of the square is approx. 1.5 μm × 1.5 μm.
Courtesy of W. Heckmann.

The rubber particles in HIPS generally have a mean diameter of 0.5 – 9 μm. They thus scatter visible light and the transparency of the PS molding materials is lost. Sequential anionic block copolymerization of styrene and butadiene allows the production of transparent [3, 4]. Phase separation of the different blocks occurs. Typically lamellar or similar impact resistant molding materials, also called styrene block copolymers (SBC) structures are formed instead of discrete particles (Fig. 2). The thickness of the layers is far less than the particle size in HIPS, so that light scattering does not occur at the phase boundaries.

Styrene Copolymers. Styrene can be copolymerized with many other monomers. Styrene – acrylonitrile molding materials, in particular, have achieved great economic importance in transparent and rubber-modified forms (SAN [*9003-54-7*], Chap. 2; ABS [*9003-56-9*], Chap. 5). Compared with the pure styrene polymers they have advantages with regard to hardness, strength, and resistance to heat distortion and environmental stress cracking. However, these advantages are offset by a higher price and more difficult processing.

Copolymers of styrene and maleic anhydride [*9011-13-6*] (Section 4.3) have a softening point that is up to 30 °C higher than that of PS molding materials. These products are used in the form of foams in the automotive industry (e.g, as interior headliners).

Polystyrene Foams. Expandable polystyrene (EPS) is the starting material for PS hard foam materials. It is produced from polystyrene by the addition of ca. 6 % of a low-boiling hydrocarbon (e.g., pentane) as the foaming agent. Extruded polystyrene (XPS) foams are produced from polystyrene and a blowing agent, e. g., carbon dioxide. Foamed polystyrene is discussed in detail elsewhere, → Foamed Plastics.

1.2. Production

Styrene. The properties and production of the raw material styrene are described elsewhere (→ Styrene). The styrene used for polymerization should have a purity greater than 99.6 % because the contaminants arising from the production process, mainly ethylbenzene, cumene, and xylenes, affect the molecular mass of the polystyrene. Commonly, purities of 99.9 % or more are used.

For storage and transport styrene is stabilized with inhibitors such as 4-*tert*-butylcatechol to prevent polymerization at low temperatures. These inhibitory radical scavengers must be removed by distillation or adsorption on alumina.

Polymerization. Styrene can function as an electron donor or an electron acceptor. It can therefore be polymerized by radical, cationic, or anionic mechanisms, or by coordination propagation steps.

The industrial polymerization of styrene to PS and HIPS molding materials is carried out exclusively by a free radical mechanism. The chain reaction does not necessarily have to be started by the addition of radical-forming, readily decomposing initiators because styrene itself can form polymerization-initiating radicals [5]. The propagation mechanism for the chain growth proceeds by addition of further monomer to the radical chain end. Growth of the radical chain is mainly terminated by recombination. With increasing temperature, disproportion and back-biting (see → Polyolefins, Section 1.3.1.1) followed by β-scission [6] play an increasing role. The growth of a chain proceeds within seconds; the gross rate is largely determined by the radical initiation reaction. Average molecular masses between 100 000 and 400 000 are obtained within a short time. Molecular masses are mainly controlled by reaction temperature, chain-transfer agents — including solvents — and by initiators. The kinetics of the process are well understood [7] and may be modeled by commercially available software.

Cationic polymerization of styrene (e.g., by strong Lewis acids such as $AlCl_3$, $HClO_3$, or BF_3) is unimportant industrially because control of the molecular mass is difficult. Very small quantities of very low molecular mass polystyrene are synthesized via such routes.

Transparent HIPS (SBC) is, however, produced industrially by anionic block copolymerization of butadiene and styrene. Organolithium compounds (e.g., *n*-butyllithium) are used as initiators. The monomers and solvent used in anionic polymerization have extremely high pu-

rity requirements. The polymerization gross rate is higher than that of the radical chain reaction due to the simultaneous growth of all initiated chains. Polymerization is carried out at low temperature in solution to enable the reaction to be controlled.

The coordination polymerization of styrene with conventional Ziegler catalysts produces a sterically ordered, isotactic polymer. These highly ordered chains can form polymer crystals. The melting temperature of the crystalline zones of isotactic polystyrene is ca. 230 °C. The rate of crystallization is, however, so low that this property cannot be exploited industrially [8].

Syndiotactic polystyrene crystallizes very rapidly and is produced by using special titanium – aluminoxan catalysts [9, 10]. The melting temperature of the syndiotactic sequences is ca. 270 °C. The material has found limited use in heat-resistant applications, often glass-fiber reinforced or blended with polyamide.

HIPS Synthesis. Rubbers used for HIPS synthesis are medium-*cis*-polybutadienes with a glass transition temperature around – 85 °C. They are obtained by butyllithium-initiated anionic polymerization of butadiene. Usually the polybutadienes are long-chain branched to prevent cold flow during storage. Other rubbers (e. g., high-*cis* grades, styrene – butadiene block copolymers, EPDM rubbers) may be also employed, but have less significance.

The synthesis of HIPS requires careful control of the rubber particle size and morphology. Initially, the solution consists of polybutadiene rubber dissolved in styrene and further additives such as diluents, chain-transfer agents, or initiators. With the onset of polymerization, the polystyrene forms a separate phase. Styrene and optional diluents are the common solvents for the elastomer and the polystyrene phase (oil-in-oil emulsion). The polystyrene phase grows at the expense of the rubber phase with further conversion. The rubber phase initially is the continuous phase and remains so if unstirred. In a stirred reactor, phase inversion occurs, largely depending on the phase volume ratios and viscosities of the two phases. The reaction conditions during phase inversion determine the rubber morphology and particle size to a large extent.

Simple blending of polystyrene and polybutadiene leads to a mechanically inferior product. The mechanical strength of HIPS is supported by polystyrene molecules, which are grafted onto rubber molecules. Grafting occurs especially at low styrene conversions, when the volume of the polystyrene phase is still small. Quantity and nature of these copolymers have big impact on the particle size and morphology of the HIPS rubber particles [11, 15].

1.2.1. Bulk Polymerization

Currently, PS and HIPS molding materials are mainly produced by continuous polymerization processes. The polystyrene product has consistent quality, high purity, and a low residual monomer content (generally less than 500 ppm monomeric styrene). The most difficult task from an industrial standpoint is the control of the highly viscous melt and the removal of the heat of polymerization (71 kJ/mol).

Solvents such as toluene or ethylbenzene are frequently present in small proportions (typically 5 – 15 %) to provide better control of the polymerization rate, the viscosity of the polymer melt, and the cross-linking of the rubber phase. This technique is known as *solution polymerization*. Due to the limited quantities of the diluent, the processes are often also referred to as *continuous bulk polymerization*. The solvent and the unreacted monomer must be removed by degassing. They are generally recovered, optionally purified and transferred back to the feed. In a running continuous operation, solvents are in essence introduced via styrene impurities (mostly ethylbenzene).

The plant setup generally comprises a polymerization section, a degassing and solvent recovery section, and a pelletizing section.

The most common reactor for *PS molding materials* is an ebullient single stirred-tank reactor. A second stirred-tank reactor or a tubular plug-flow reactor may be used to increase conversion. PS molding materials may also be produced in more complex reactor configurations like HIPS units.

HIPS plants generally consist of a series of three to five reactors, split into a prepolymerization and postpolymerization section. In the prepolymerization section phase inversion takes place, and rubber morphology and particle size are largely adjusted. Various reactor designs

Figure 3. Various reactor configurations for HIPS production
a), b), d), e), g) Stirred-tank reactors; c) Horizontal plug-flow reactor; f) Tower reactors
Reproduced from [14] with permission of Hanser Publishers.

have been proposed for this part of the plant. Common are one or two stirred-tank reactors, tower reactors, loop reactors with static mixers, or combinations of these. The reaction is typically carried out at 100 – 150 °C to 15 – 30 % conversion. The postpolymerization part commonly consists of several plug-flow type reactors to achieve high styrene conversions, but continuous stirred-tank reactors may be used as well. Common temperatures are 140 – 190 °C in this part of the plant. Figure 3 shows several common reactor configurations.

In the *continuous stirred-tank reactor* part of the heat is removed by means of reflux cooling. The heat of polymerization causes part of the styrene to evaporate. The gaseous monomer is condensed in condensers with large surface areas and recycled back to the reactor. The prerequisite for this type of heat removal is effective mixing of the reactor contents. Anchor stirrers, impellers, or helical ribbon agitators are commonly used. The reaction temperature is the most important parameter affecting the molecular mass of the polystyrene and thus the properties of the product. It is controlled by varying the

pressure and thus the boiling point of styrene in the stirred tank. The temperatures in the reactors are between 100 and 170 °C, corresponding to pressures of ca. 0.5 – 2 bar.

The reactor feed can also be used to remove heat of polymerization. Reactors converting more than 40 % of the styrene feed usually need additional cooling. The lower solid content of the HIPS prepolymerization reactors, on the other hand, necessitates preheating of the reactor feed.

Tower reactors are equipped with special baffles in which a cooling agent circulates to ensure the removal of the heat of polymerization. Different temperature zones can be set up in a reactor by adjusting the temperature of the cooling agent. The tower reactors are also equipped with agitator blades.

Tubular reactors with static mixing elements and cooling are also in use. Adiabatic or isothermal tubular reactors are sometimes used for high conversions. Also known are axially segmented and agitated tubular reactors operating under reflux.

The polystyrene melt leaving the reactor section has a concentration of 60 – 90 %. Unreacted styrene monomer and solvent are removed by flash devolatilization. The polymer is fed into an evacuated, heated vessel where the volatile components evaporate, the melt is then pumped out. The styrene – solvent mixture formed is recycled to the first reactor. A small fraction must be discarded, however, to avoid increasing the concentration of styrene contaminants.

A second flash tank or another degassing unit (e.g., falling strand degassers, steam strippers, thin-film evaporators, degassing extruders) may be used to further decrease content of volatile compounds.

The polymer melts can be mixed with additives (e.g., dyes, stabilizers, or lubricants) by using static or mechanical mixing equipment.

Degassing of the polystyrene melt is followed by pelletization. In extrusion pelletization the polymer is forced through a perforated disk in continuous strands. The necessary pressure is applied by means of the discharge pump in the degassing unit or by an extruder. The strands are cooled in a water bath and cut into cylindrical pellets.

Underwater and water-ring pelletizing systems are also used and yield lentil-shaped pellets.

The pellets can be coated with an externally applied lubricant (e.g., zinc stearate or *N,N'*-ethylene-bis(stearamide)) to improve the sliding properties.

1.2.2. Suspension Polymerization

Suspension processes are chiefly used for the production of expandable polystyrene. PS molding materials may be produced by this process when the blowing agent is omitted. The combined bulk – suspension process is sometimes still used for HIPS production.

In suspension polymerization styrene is dispersed in water in the form of small droplets by stirring. The addition of suspension agents such as poly(vinyl pyrrolidone), poly(vinyl alcohol), alkaline-earth phosphates, or celluloses is necessary to stabilize the organic phase. Polymerization must be started with radical-forming initiators because the process temperatures are considerably lower than those of continuous bulk polymerization (80 – 110 °C).

The main advantage of suspension polymerization is that the heat of polymerization can easily be removed via the aqueous phase. A high degree of conversion can also be achieved.

Generally, however, the polystyrene beads must be repelletized after separation of the water and drying to satisfy market requirements with regard to processing of the molding materials (e.g., injection molding equipment). Additives and dyes can be incorporated during regranulation.

In the case of HIPS, suspension polymerization must be preceded by bulk polymerization to ensure that rubber particles are formed. The reaction can only be carried out in suspension after the formation of the disperse polybutadiene phase. The product has comparable material properties to HIPS produced by the bulk process.

The batch suspension process for styrene polymerization has been gradually replaced by the more economically favorable continuous bulk processes. Very few of the older plants based on batch suspension technology are still run commercially.

Table 1. Physical properties of PS and HIPS resins

Property	Test method	Typical values	
		PS resins	HIPS resins
Density, g/cm^3	DIN 53 479 ASTM D 792	1.05	1.03 – 1.05
Melt flow index (200 °C/5 kg), g/10 min	DIN 53 735 ASTM D 1238/G	1 – 30	2 – 20
Tensile modulus, MPa	DIN 53 457 ASTM D 638	3000 – 3400	1600 – 2800
Yield tensile strength, MPa	DIN 53 455 ASTM D 638	35 – 60	20 – 45
Tensile elongation at break, %	DIN 53 455 ASTM D 638	1.5 – 3	25 – 70
Ball indentation hardness, MPa	DIN 53 456 ISO 2039	150 – 160	75 – 140
Flexural strength, MPa	DIN 53 452 ASTM D 790/1	60 – 120	35 – 80
Charpy impact strength, kJ/m^2	ISO 179	10 – 25	35 – no break

Dissipation factor (1 MHz)	DIN 53 483 ASTM D 150	$(1 – 4) \times 10^{-4}$	$(2 – 8) \times 10^{-4}$
Thermal coefficient of linear expansion, K^{-1}	DIN 53 752	$(6 – 8) \times 10^{-5}$	$(8 – 10) \times 10^{-5}$
Refractive index	DIN 53 491	1.59	

1.3. Properties

1.3.1. Chemical Properties

The chemical properties of atactic PS and HIPS are similar.

Under certain conditions oxidizing acids lead to oxidative degradation. However, the molding materials are resistant to dilute acid, alkali, and salt solutions. Exposure to UV radiation in the presence of oxygen causes yellowing and embrittlement, particularly in HIPS modified with polybutadiene. Reactions at the remaining double bonds bring about a gradual loss in elastic properties of the soft components. This damage can be suppressed but not completely inhibited by the addition of light stabilizers. Polystyrene is therefore not generally used in areas of application where weather resistance is required.

The replacement of polybutadiene rubber by EPDM rubber and the addition of special antioxidants lengthen the service lifetime of materials exposed to weathering by a factor of 15 – 20.

Oils and fats (particularly important in the food packaging sector) produce stress cracking. This can, however, be effectively counteracted by a range of measures [13], for example, by moderately increasing the average particle size to more than 5 μm.

The self-ignition temperature of PS and HIPS is 490 °C. Polystyrene articles are generally classified as being moderately flammable (DIN 4102) and as slow-burning (Underwriters Laboratories UL 94 HB). The flammability of special HIPS molding materials can be reduced considerably with additives (e.g., organobromine compounds) to give products that are classified as having a low flammability. The main area of application for these products is in the electrical sector. They are also increasingly being used for housings for technical appliances (e.g., photocopiers, televisions).

1.3.2. Physical and Processing Properties

Polystyrene, being a linear hydrocarbon chain with phenyl side groups linked, on average, to every second carbon atom, dissolves in aromatic hydrocarbons (toluene, ethylbenzene), halogenated hydrocarbons, aliphatic ethers (tetrahydrofuran), esters (ethyl acetate), and ketones

Figure 4. Summary of property relationships of commercial mass-produced HIPS
Reproduced from [12] with permission of The Dow Chemical Company.

(butanone), but not in aliphatic hydrocarbons (hexane) and alcohols (methanol). A summary of the solubility behavior of polystyrene can be found in [12].

The most important physical data for PS and HIPS are given in Table 1.

Special PS molding materials are available with specific property profiles for different processing technologies such as injection molding, extrusion, or thermoforming.

The mechanical and rheological behavior of polystyrene is predominantly determined by its average molecular mass (normally 150 000 – 400 000). The strength improves with increasing chain length but the melt viscosity increases making processing more difficult. Lubricants such as butyl stearate or paraffinic oil can be added to lower the melt viscosity of PS and HIPS. However these agents also lower the softening point.

PS grades with very good or good flow properties are mainly used for processing in injection molding machines. High molecular mass grades with higher strength and resistance to heat distortion are preferred for extrusion of films and sheets.

In extrusion and injection molding, the polystyrene melt is forced through narrow nozzles or slits. The polymer molecules orientate themselves parallel to the flow direction due to the high shear rate. The melt often solidifies in the mold so quickly that this initial orientation cannot be reversed by molecular diffusion. Polystyrene end products may therefore display anisotropy of their mechanical properties parallel and perpendicular to the processing direction.

Tensile properties are much increased in parallel to the processing direction, while they are generally weakened perpendicularly to it. Biaxially oriented polystyrene has increased mechanical strength over the entire film. It may dissipate mechanical energy by a so-called "shear yielding" rather than the more common and less efficient "crazing" mechanism.

The impact resistance of HIPS is higher than that of PS due to the rubber component, but transparency is lost [exception: transparent styrene – butadiene multiblock copolymers (SBC) produced by anionic polymerization (Section 1.1)]. Processing properties are not altered significantly by the polybutadiene phase. However, the softening point, the modulus of elasticity, and the hardness are lower than those of PS molding materials.

In HIPS, the rubber phase (generally polybutadiene) is distributed in the form of discrete particles in the polystyrene matrix. The most important parameters affecting the properties of the end products are the rubber content, morphology, average particle size, particle-size distribution, and the degree of cross-linking of the polybutadiene phase (Fig. 4).

Rubber Content. The HIPS grades from different producers may be classified according to their polybutadiene (PB) content: semi-impact-resistant (ca. 3 – 6 % PB) and impact-resistant (6 – 10 % PB). The real criterion is not the rubber content, but the gel content that is obtained with a given rubber content (i.e., the mass fraction of the disperse phase including the polystyrene enclosed within the particles and grafted onto the polybutadiene chains) [14]. The gel content is roughly three to four times the quantity of rubber added.

Rubber Morphology. A wide range of different particle morphologies can be obtained depending on the chemical composition of the rubber and the polymerization conditions. Standard HIPS grades containing polybutadiene usually consist of cellular particles (Fig. 1). If part of the polybutadiene is replaced by styrene – butadiene block copolymers, coils, mazes, shell, or capsule particles are formed [15].

Particle Size and Particle-Size Distribution. The particle-size spectrum of the rubber phase is the factor determining the impact resistance of the molding materials. Commercial grades have average particle sizes in the range 0.5 – 9 μm. The highest mechanical efficiency is in the range 1.5 – 3 µm. If the particles are significantly larger, less crazes and less cavitation can be supported by the same rubber quantity [16 17]. Grades with particles sizes > 5 μm have increased environmental stress crack resistance. Rubber particles smaller than 1 µm are less efficient in craze initiation. Such HIPS grades have reduced impact strength and are used for high gloss applications.

The average particle size depends on the polymerization conditions during phase inversion. The most important parameters listed below can be modified as required:

1) The ratio between the solution viscosities of the disperse polybutadiene and homogeneous polystyrene phases
2) The shear force applied to the polymerizing material via the agitator
3) The surface tension between the two phases [18]—largely affected by the degree of grafting

Degree of Cross-Linking. Another important parameter is the cross-linking density of the polybutadiene phase. The rubber chains must be cross-linked with one another to a certain degree so that they can resist the shear forces used in subsequent processing, thus guaranteeing a stable particle form. However, the cross-linking density must not be too high because this would lead to the loss of the desired rubber-elastic properties. Cross-linking is a thermally initiated radical reaction and occurs mainly at high degrees of conversion and in the degassing section of the polymerization plant. The parameters in this process step (residence time, temperature) must therefore be adjusted to give the desired degree of cross-linking in the end product.

1.4. Processing and Uses

PS and HIPS molding materials are processed using molding processes generally used for thermoplastics (e.g., injection molding, extrusion, or thermoforming). About 50 % of the total quantity is processed with screw injection molding machines at 200 – 280 °C.

Films and sheets are produced by extrusion at ca. 200 °C with broad-slit dies. Thermoforming is used to produce articles such as refrigerator

linings from sheets and yogurt cups and disposable tableware from films.

PS and HIPS molding materials are mutually compatible and can be mixed with one another in all proportions. The properties of the mixtures depend on the proportions of the components.

The main areas of application of PS and HIPS molding materials are in packaging, technical items, household and consumer goods, and refrigeration equipment. Roughly two thirds of PS and HIPS are consumed for packaging and for technical items. Packaging accounts for more than 50 % of the consumption in Western Europe and the United States, where technical items represent 20 – 25 % of the market. In Asia, 20 – 25 % of the material goes to the packaging sector, while more than 50 % are used for technical items. Asia accounts for more than 40 % of the total polystyrene consumption, the NAFTA region and the European Union for about 25 % each (2005). Recent annual growth rates have been ca. 2 %.

Technical items include housings for television, computers, printers, air conditioners and the like, electrical appliances, computer accessories, and sanitary ware.

Household and consumer goods include toys, containers, furniture, disposable tableware, and cups for drink vending machines. Polystyrene is used for the packaging of compact discs, audiocassettes, foods and pharmaceuticals. Polystyrene is especially suitable for the packaging of dairy products. Biaxially oriented polystyrene and PS blown film are used for display packaging, wrap film, and envelope windows.

PS and HIPS molding materials do not affect odor or taste and are licensed worldwide for contact with foods. Legal requirements in individual countries specify permitted concentrations of materials used in production and processing. All standard commercial PS and HIPS molding materials comply with these guidelines.

Trade Names and Producers. PS and HIPS molding materials are produced by more than 100 raw materials manufacturers throughout the world who offer an extensive range of products classified according to strength, processing behavior, and dimensional stability when subjected to heat. Total installed capacity is about 15×10^6 t. Examples of trade names are given in alphabetical order by producer below:

Polystyrol	BASF Aktiengesellschaft, Germany
Starex	Cheil Industries, Korea
Polyrex	Chi Mei, Taiwan
-	Chevron – Phillips Chemical Comp.
Styron	Dow Chemical, USA
Edistir	Enichem Polimeri, Italy
-	Estizulia, Venezuela
-	Innova, Brazil
-	Ineos, Great Britain
-	Kumho, Korea
LG	LG Chemicals, Korea
-	Japan Polystyrene
-	Nizhnekamskneftekhim, Russia
-	Nova Chemicals, Canada
-	Resirene, Mexico
-	PS Japan
SC	Supreme Petrochem. Ltd., India
PS	Sabic, Saudi Arabia
-	Secco, China
-	Shantou, China
Lacqrene	Total, France
-	Videolar, Brazil
-	Wuxi Wei Da, China

The producers (and trade names) of transparent HIPS molding materials are Asahi Chemicals, Japan (Asaflex), BASF, Germany (Styrolux); Chevron – Phillips Chemicals, USA (K-resin); Chi Mei, Taiwan (Kibiton), Denka, Japan (Clearen), and Kraton Polymers, USA (Kraton). Total installed capacity is about 0.5×10^6 t (2006).

Syndiotactic polystyrene is produced by Idemitsu Petrochemical, Japan, under the trade name Xarec. Installed capacity is 5000 t/a (2001).

1.5. Quality Specifications

Most PS and HIPS molding materials are processed automatically which means that product quality must be as uniform as possible. Quality assurance systems (ISO 9000 – 9004) are common in the production of molding materials to guarantee maximum uniformity. The ISO standard specifies the quality of all raw materials, the production conditions, and the properties of the end products.

The rheological, mechanical, thermal, and electrical properties of the molding materials are defined in ISO 1622–2 (PS) and 2897–2 (HIPS). The Vicat softening temperature (VST B/50, ISO 306), the melt flow index (MFI 200/5,

ISO 1133), and the impact resistance (Charpy, ISO 179) are among the most important properties. National standards such as ASTM or DIN (Table 1) largely correspond to the ISO standards.

1.6. Storage and Transportation

The storage and transportation of PS and HIPS molding materials do not pose any special problems. They are subject to the general fire protection requirements applicable to solid combustible materials such as wood. Roofed sheds or silos are suitable for storage. Polystyrene is not moisture-sensitive, but must be dry for processing. PS and HIPS molding materials are transported in paper or polyethylene bags, in large cardboard containers (capacity ca. 1 t), in silo vehicles or containers. In the NAFTA region, rail cars (hopper cars, capacity 80 t) are also used.

1.7. Recycling

Waste PS and HIPS can be reutilized in various ways. In *material recycling* the molding materials are broken into smaller pieces, melted, and reprocessed to give finished products. *Chemical recycling* involves the breaking up of the polymer chain into lower molecular mass components which can be used as raw materials for chemical processes. In *thermal recycling* the plastic is incinerated and the liberated energy is used, for example, as process heat or for general heating purposes. See also → Plastics, Recycling.

Material Recycling. Recycling of industrial waste, such as trims and scrap, is not problematic. Polystyrene end products can also be recycled after use provided that the material can be cleaned and sorted into grades. In no case, however, should food packaging be produced from this recycled material. Some countries stipulate legal quotas for material recycling of plastics.

Chemical Recycling. Two processes are in the development stage: pyrolysis and cleavage by hydrogenation cracking. Both processes can be applied to pure plastics fractions (e.g., polystyrene) and mixtures of plastics.

Pyrolysis involves the cleavage of long-chain molecules at high temperatures (500 – 900 °C) with the exclusion of oxygen [22]. In hydrogenating cleavage the polymer chains are broken up under higher pressure at ca. 400 °C, and in the presence of hydrogen, into volatile saturated compounds. Both processes yield a nonspecific spectrum of products (60 – 80 % of styrene and ethylbenzene, respectively), which can be used as feedstock for other petrochemical processes.

Thermal Recycling. In the presence of sufficient oxygen, polystyrene burns almost completely to give carbon dioxide, water, and a small amount of nontoxic ash residue. The enthalpy of combustion (41 MJ/kg) is close to the energy content of fuel oil (43 MJ/kg). In modern waste incineration plants, polystyrene comprises part of the plastics fraction of household waste, adherence to the necessary combustion conditions is guaranteed.

1.8. Environmental Aspects

PS and HIPS molding materials are not water soluble. No gaseous or liquid components are liberated during transportation and storage. Liquid and gaseous styrene must, however, be handled safely during production processes. Polymerization is therefore carried out in closed systems. The maximum permitted workplace concentration of styrene is between 10 and 50 ppm (42 – 210 mg/m^3) in all important producer countries.

In bulk polymerization processes, the product only comes into contact with water during the cooling of the extruded strands. Contamination of the water does not occur. In the suspension process, polymerization takes place in an aqueous medium and the wastewater must be treated by using standard sewage technology.

In the processing of PS and HIPS, small quantities of styrene are liberated above ca. 280 °C as a result of the residual monomer content and of thermal degradation. The styrene can be removed by special ventilation devices; however, normal room ventilation is usually adequate to ensure compliance with workplace concentration limits.

2. Styrene – Acrylonitrile (SAN) Copolymers

Many applications requiring stiffness and transparency are served by polystyrene, a moderately priced commodity thermoplastic (Chap. 1). A mature market has also continued to thrive for resins offering a better balance of optical clarity, rigidity, good chemical and heat resistance, high strength, and flexible processing. One class of thermoplastics having these properties is the styrenic copolymers. The following four copolymers continue to have growing commercial importance:

1) Styrene – acrylonitrile (Chap. 2)
2) α-Methylstyrene – acrylonitrile (Section 4.1)
3) Styrene – methyl methacrylate (Section 4.2)
4) Styrene – maleic anhydride (Section 4.3)

These copolymers are produced commercially by free-radical polymerization [23]. Their specific properties are determined by their molecular mass and composition. The initial concentration of the two monomers (M_1 and M_2) prior to initiation of polymerization must be carefully chosen to give the required copolymer composition for the finished product. Techniques are available for calculating the correct monomer concentration that utilize parameters known as reactivity ratios (r) that reflect the relative reactivity of each monomer with the free-radical end of the growing chain [24]. The dependence of the copolymer composition on the monomer concentration for each of the above styrene copolymers is given in Figure 5.

The styrene copolymers having the greatest commercial importance are the styrene – acrylonitrile (SAN) copolymers [*9003-54-7*]. Incorporation of acrylonitrile improves heat resistance, toughness, chemical resistance, and barrier properties when compared against polystyrene. The SAN polymers can be used by themselves in applications requiring transparency, or they can be toughened by incorporation of rubber particles. Use of butadiene rubber gives acrylonitrile – butadiene – styrene (ABS) polymers (see Chap. 5).

The acrylonitrile (AN) levels in commercial SAN polymers fall into two ranges. The lower range (20 – 35 wt %) covers most injection-molded articles, and the higher range (60 – 85 wt %) represents a small but growing market for barrier plastics where low gas permeability is needed for packaging of food and beverages (see Chap. 3).

Figure 5. Composition diagram for common styrene copolymers
a) Styrene (M_1) – acrylonitrile (M_2) (r_1= 0.40, r_2= 0.04); b) Styrene (M_1) – maleic anhydride (M_2) (r_1= 0.04, r_2= 0); c) α-Methylstyrene (M_1) – acrylonitrile (M_2) (r_1= 0.10, r_2= 0.06); d) Styrene (M_1) – methyl methacrylate (M_2) (r_1= 0.59, r_2= 0.54)

2.1. Production

The relative reactivities of styrene and acrylonitrile differ. Therefore, the polymer composition also differs from the monomer composition, except at the azeotrope (ca. 24 wt % acrylonitrile). This, along with the fact that acrylonitrile is soluble in water, requires special considerations for the various production methods.

Using reactivity ratios [25] and Equation (1) [26] for two monomers M_1 and M_2:

$$C = \frac{P-1+\sqrt{(1-P)^2+4Pr_1r_2}}{2\,r_1} \qquad (1)$$

C = molar ratio M_1/M_2 in the monomer mixture
P = molar ratio M_1/M_2 in the copolymer
r_1 = reactivity ratio for monomer 1
r_2 = reactivity ratio for monomer 2

the monomer – polymer composition curve can be determined for SAN and other common

copolymer pairs (Fig. 5). Reactivity ratios (styrene: r_1 = 0.4 and acrylonitrile, r_2 = 0.04; Fig. 5.) imply that a mixture of about 75 wt % styrene and 25 wt % acrylonitrile shows no compositional drift ("azeotropic composition").

Reactivity ratios are a function of temperature [27] and the composition curves should be adjusted if the temperature range during manufacture is wide. This is not as critical when the azeotrope composition is approached.

Maintaining tight composition control of SAN is important to obtain acceptable optical and mechanical properties. Differences of a few weight percent in the SAN composition can result in incompatibility [28]. For example, addition of 2 wt % SAN with 32 % acrylonitrile to SAN with 24 % acrylonitrile leads to hazy material. As conversion increases, severe composition drift occurs (Fig. 6) unless corrective actions are taken to replenish the more reactive monomer [29].

Figure 6. Approximate compositions of SAN copolymers formed at different conversions, starting with various monomer mixtures [29]
Styrene : acrylonitrile weight ratio
a) 35/65; b) 70/30; c) 76/24; d) 90/10

Commercially, SAN is produced worldwide by emulsion, suspension, and continuous bulk technologies [30]. These methods are described in detail elsewhere, → Polymerization Processes. The majority (85 %) of SAN is used captively as the matrix component for ABS. Most SANs used for the manufacture of ABS contain 24 – 32 wt % acrylonitrile. The properties of ABS can be influenced by the composition and molecular mass distribution of the SAN, which are manipulated by the polymerization method employed to make the SAN. This is discussed in detail in Section 5.3.2.

SAN materials sold as finished products are almost exclusively made by continuous bulk methods which results in superior optical properties. Also, continuous bulk technology is the most cost efficient and generates the least waste of the three methods.

Figure 7. Process for the continuous bulk and solution polymerization of SAN [31]
a) Reactor; b) Condenser; c) Condensate receiver; d) Recycle pump; e) Melt pump; f) First-stage devolatilizer; g) Second-stage devolatilizer; h) Discharge screw pump; i) Water bath; j) Pelletizer; k) External lube; l) Screen; m) Silo

Figure 7 shows an example of the manufacture of SAN via continuous bulk polymeriza-

tion. The process consists of continuous feeds to one or more reactors (a), followed by devolatilization units (f, g) and pelletizer (j). Unreacted monomers and solvent are recycled to maintain conversion and composition at desired levels. The technology is very similar to that employed for PS molding materials (see Section 1.2.1).

The reactor(s) can be plug flow or partially filled types, cooled by jacket and/or reflux [31, 32]. Adequate agitation is critical for proper temperature and composition control. Polymerization temperatures range from 80 – 170 °C, depending on the process configuration and whether chemical or thermal initiation is used. Conversion ranges from 30 to 70 %.

Devolatilization is usually accomplished via wiped-film or falling-strand type units, but can also be done with a devolatilizing extruder. To achieve the low levels of residual monomer required to meet food contact applications, devolatilization is usually done in a two-stage process with different vacuum levels.

2.2. Properties

SAN copolymers with acrylonitrile contents between 20 and 35 wt % are transparent plastics having better mechanical and chemical resistance properties than polystyrene, thus enabling SAN to command a premium price. Properties for commercial grades of polystyrene and SAN are compared in Table 2 [33]. Next to a higher rigidity and impact resistance, the SANs are stronger and more scratch resistant and have a better heat resistance.

SAN can be reinforced with glass fiber to give higher stiffness, breaking strength, and notched impact strength [34, 35]. The effect of adding 20 % glass fiber to SAN is shown in Table 3 [36].

Table 3. Comparison of properties of filled and unfilled SAN

Property	Unfilled	Filled with 20 % glass fiber
Tensile strength, MPa	69 – 76	74 – 83
Elongation at break, %	2 – 3	1.4 – 1.9
Tensile modulus, GPa	3.3 – 3.9	8.3 – 11.7
Notched Izod impact strength, J/m	21.4 – 32	133 – 160
Heat deflection temperature, °C at 1.82 MPa load	101 – 104	99 – 110
Density, g/cm^3	1.07 – 1.08	1.22 – 1.40

The conventional method for making glass-fiber-reinforced SAN is to mix the polymer pellets and glass fiber in an extruder, followed by injection molding of the glass-filled pellets. This approach suffers from the inadvertent reduction in glass-fiber length (12 mm) to ca. 0.4 – 0.5 mm.

An alternative approach is to make a glass concentrate (collimate) by polymerizing the SAN in the presence of the glass fibers, and then blending the collimate with SAN pellets. Commercial collimates are available containing 80 % glass [37]. The glass fiber length in the final product is about 1 mm, and superior reinforcing properties are claimed with the collimate approach. The SAN collimate can be added to other thermoplastic resins.

The heat resistance (softening temperature) of typical commercial grades of SAN is ca. 5 – 6 °C higher than that of polystyrene (Table 2), thus allowing SAN to resist softening when exposed to boiling water. The softening of styrene polymers (and copolymers) is a consequence of the glass to rubber transition that occurs when glassy polymers are heated [38].

Addition of acrylonitrile to the styrene chain continuously increases the glass transition temperature (T_g) until a level of approximately 35 wt % acrylonitrile is reached. The T_g then falls with further addition of acrylonitrile [39]. The location and width of the glass transition for any composition is affected by the polydispersity of the molecular mass.

Commercial SANs contain oligomers left from polymerization which lower the T_g via plasticization. Removal of the oligomers in a commercial SAN (24 % acrylonitrile) increases the glass transition from 108.5 to 114.5 °C [40]. Therefore, any commercial SAN that is carefully treated to remove oligomers will benefit by having a higher heat resistance. The oligomers can be reduced by polymerizing at low temperatures ($<$ 120 °C) or by stripping them out during devolatization and subsequent purging from the recycle stream. If a large increase in heat resistance over polystyrene is needed, it is preferable to use the α-methylstyrene – acrylonitrile copolymers (see Section 4.1).

SAN has a slight yellow color in comparison to clear plastics such as polystyrene, acrylics, and polycarbonate. This color arises from cyclic chromophores associated with the acrylonitrile

Table 2. Comparison of the physical properties of standard polystyrene and SAN copolymers

Property	DIN test method	Standard polystyrene	SAN copolymers (20 – 35 wt % acrylonitrile)
Density, g/cm^3	53 479	1.05	1.08
Tensile strength, MPa	54 355	50 – 65	75 – 85
Tensile elongation to fail, %	53 455	2 – 4	5
Flexural strength, MPa	53 452	100 – 110	110 – 140
Flexural modulus, MPa	53 457	3200 – 3400	3600 – 3800
Impact resistance, kJ/m^2	53 453	15 – 20	20 – 25
Notched impact test, kJ/m^2	53 453	2 – 3	3 – 4
Heat resistance, °C	53 461, version B	80 – 100	90 – 105
Thermal conductivity, kJ m^{-1} h^{-1} K^{-1}		0.71	1.17
Linear thermal expansion coefficient, K^{-1}		$(6 – 8) \times 10^{-5}$	$(6 – 8) \times 10^{-5}$
Dielectric constant	53 483	2.5 – 2.7	2.9 – 3.1
Dielectric loss factor	53 483	$(1.8 – 2.1) \times 10^{-4}$	$(6 – 9) \times 10^{-3}$
Specific resistance, $\Omega \cdot$ cm	53 482	$> 10^{16}$	$> 10^{16}$
Dielectric strength, kV/mm	53 481	> 100	> 50
Water absorption, 24 h, %	53 472	0.1	0.2 – 0.6
Processing temperature, °C		150 – 260	175 – 300

segments, and it becomes stronger as the acrylontrile content increases. Some new commercial, "water-white" grades have been introduced for applications requiring minimum yellowness [27, 28]. The reduction in color is brought about by lowering the level of acrylonitrile and fine-tuning the polymerization process to reduce haze and eliminate contaminants.

One negative consequence of the addition of the acrylonitrile to the styrene chain is an increase in melt viscosity. The nitrile groups in acrylonitrile are strong dipoles, and, as the acrylonitrile level increases, the dipolar attraction between the acrylonitrile groups increases the melt viscosity. This can be compensated for by increasing the processing temperature (Table 2). However, raising the temperature also increases the yellow color, so a compromise must be reached between processibility, properties, and color.

The polar nature of the acrylonitrile also results in slight deterioration of electrical properties in comparison to polystyrene (Table 2). SAN still has adequate properties as an insulation material.

Excellent chemical resistance is a very important feature of SAN resins. They are resistant to aliphatic hydrocarbons, nonoxidizing acids, alkali, vegetable oils, foods, some alcohols, and detergents. Many of these materials readily attack polystyrene, but the polarity of the acrylonitrile groups in SAN is responsible for better resistance. SAN resins are attacked by some aromatic hydrocarbons, ketones, esters, and chlorinated hydrocarbons [41]. The moisture absorption of SAN is also slightly higher (Table 2), again because of the polarity of acrylonitrile.

The UV resistance of SAN is not exceptionally good, due to the styrene unit. However, the addition of UV stabilizers improves the UV resistance to the point that some SAN grades are used for glazing and other outdoor applications [41].

2.3. Processing

SAN resins can be processed by all methods common to thermoplastics, with injection molding being the most prevalent [42 – 44]. The resins are slightly hygroscopic and should therefore be dried prior to processing. Since SAN resins are immiscible with most other polymers it is important that the equipment be thoroughly purged prior to processing.

Injection molding barrel operating temperatures are typically ca. 220 – 280 °C, which is about 10 – 20 °C higher than is used for polystyrene. Yellowing and some mechanical property deterioration occurs if the temperature is too high or if too much regrind is used [45].

The mold should be filled as rapidly as possible. This can be accomplished by using large nozzles and gates, high pressure, fast ram, and adequate mold vents. Warm molds are necessary to achieve maximum surface gloss and improve impact strength—the warm mold lowers

the cooling rate and allows some of the flow orientation to relax before the part reaches the glassy state. Oven annealing of the part also reduces this orientation and may be required for special applications involving high mechanical stresses and pressures.

Finishing operations applicable to SAN include hot stamping, painting, screen printing, sonic welding, machining, vacuum metallizing, solvent welding, and most other operations used for ABS, acrylics, and polystyrene [46]. The good chemical resistance of SAN facilitates finishing operations requiring chemical exposure. Coloring and provision of antistatic agents, stabilizers, and flame retardants, as well as the reuse of scrap, are handled as with polystyrene (see Chap. 1).

2.4. Uses

The largest end use for SAN is as the rigid component for ABS (Chap. 5). All major ABS producers manufacture SAN for this captive use. SAN is used in the merchant market for a range of applications such as cookware, transparent parts in electronics and electrical appliances, instrument panels, sanitary and medical goods or cosmetic packaging. Chemical resistance and transparency are primary reasons for use [41, 42, 46].

The largest producers of SAN and their trade names are summarized in Table 4.

Table 4. Major producers and trade names of SAN

Producer	Trade name
BASF (Germany)	Luran
Daicel (Japan)	Cevian
Dow Chemical (USA)	Tyril
Techno Polymer Co. (Japan)	Sanrex
Polimeri (Italy)	Kostil

2.5. Blending of SAN

A new resin with unique properties may be obtained by blending (alloying) two or more polymers. Many studies have focused on SAN-based polymers as a major component of the alloy.

Commercial efforts have largely involved blending of ABS with major commercial polymers such as poly(ethylene terephthalate), polycarbonate, poly(vinyl chloride), and polyamide nylon to make resins with improved impact strength, heat resistance, and chemical resistance when compared to the individual polymers (see Section 5.12) [47]. These blends are not transparent because the rubber incorporated into the ABS for impact strength scatters light. The SAN does not become miscible with the other polymer. Rather, distinct domains of ABS and the other polymer phases remain, and the key to developing good mechanical properties is to reduce the domain size and promote good interphase adhesion [48].

Blending of SAN with other polymers to yield a transparent resin would require that the component polymers be thermodynamically miscible, alternatively the domains would have to stay below the critical size for light scattering.

Although polymers are generally not mutually miscible [47], SAN polymers show limited miscibility with poly(methyl methacrylate) [49], styrene – maleimide copolymers [50], styrene – maleic anhydride copolymers [51, 52], polycaprolactone [53], and poly(vinyl chloride) [54].

3. Barrier Resins

Acrylonitrile polymers and copolymers afford efficient barriers to gases, such as oxygen and carbon dioxide. Polyacrylonitrile [*25014-41-9*] (PAN) has the lowest permeability of any polymer, but its inherent rigidity and poor processibility (it degrades upon heating prior to melting) has spurred development of high acrylonitrile copolymers containing 60 – 85 wt % acrylonitrile.

Rubber-modified acrylonitrile – methyl acrylate copolymers are offered under the trade name Barex by Innovene. The acrylonitrile level in the Barex resin is 74 %. The copolymer is toughened by addition of styrene – butadiene rubber at a level of 10 %. The resins may be processed by all major thermoplastic processing methods.

Permeation of oxygen into food and beverages adversely affects their taste [55], and storage of carbonated beverages requires low permeation of carbon dioxide out of the bottle. The high acrylonitrile resins have much lower permeation rates than other thermoplastic packaging resins (Table 5). These high-acrylonitrile

Table 5. Permeation rates to oxygen and carbon dioxide at room temperature for polymers used in food packaging

Polymer	Permeation rate		
	Oxygen [a]	Carbon dioxide [a]	Ratio CO_2/O_2
Poly(vinylidene chloride)	0.0393	0.118	3.0
Barex 210	0.43	1.22	2.8
AN – styrene copolymer, 70–30	0.39	1.18	3.0
Poly(ethylene terephthalate)	2 – 4 [b]	4.7 – 7.8 [b]	
Poly(vinyl chloride) unplasticized	3 – 6 [c]	7.8 – 16 [c]	
Cellophane (dry, uncoated)	0.05	0.118	2.3

[b] Depends on crystallinity and orientation.
[c] Depends on compound formulation.

resins are also quite good barriers to moisture, which is another requirement for food packaging.

The effect of acrylonitrile level on permeation rates for SAN copolymers is shown in Figure 8. The highest practical limit for acrylonitrile content is approximately 80 %, at which point the copolymer begins to take on the pseudocrystalline structure of polyacrylonitrile and becomes difficult to process [56, 57].

Figure 8. Permeability of oxygen and carbon dioxide through styrene – acrylonitrile copolymers
Values for the two homopolymers, polystyrene (PS) and polyacrylonitrile (PAN), are indicated.

Barrier resins are produced by suspension or emulsion polymerization [58, 59]. Maintaining constant composition at high acrylonitrile levels requires special techniques. A certain amount of the more reactive comonomer (e.g., styrene) is held outside the reactor and fed in a controlled manner during the polymerization cycle.

As animal tests have shown acrylonitrile to be a potent carcinogen, levels of acrylonitrile in the containers must be kept exceedingly low [60].

4. Other Copolymers

Producers and trade names of other important styrene copolymers are listed in Table 6.

Table 6. Examples of producers and trade names of common thermoplastic styrene copolymers

Producer (country)	Comonomers	Trade name
BASF (Germany)	α-methylstyrene – acrylonitrile	Luran KR 2556
Nova Chemicals (Canada)	styrene – methyl methacrylate	NAS, Zylar
Arco Chemical (USA)	styrene – maleic anhydride	Dylark
Denki Kagaku Kogyo(Japan)	styrene – maleimide	Malecca
Techno Polymer Co. (Japan)	styrene – maleimide	Superex

4.1. α-Methylstyrene – Acrylonitrile Copolymers

The copolymer of α-methylstyrene (AMS) and acrylonitrile [*25747-74-4*] has a higher heat resistance and softer flow than SAN of the same acrylonitrile content. The heat deflection temperatures of the AMS – AN and SAN copolymers are 104 and 96 °C, respectively [61]. Physical properties and chemical resistance are similar to those of SAN. As with SAN, most

AMS – AN copolymers are used as diluents to make high-temperature ABS (Sections 5.1.4 and 5.3.2) and acrylonitrile – styrene – acrylate (ASA) materials. AMS – AN copolymers are extensively compatible with SAN copolymers if they both have an acrylonitrile content of ca. 30 wt % [159]. The AMS copolymer is miscible with poly(vinyl chloride) [62], and could therefore be used to make both toughened and clear blends.

The manufacturing methods used for SAN can also be used for the AMS – AN copolymer. However, AMS reacts more slowly than styrene, greatly increasing the process residence times for a given acrylonitrile content. It is also more difficult to obtain high molecular mass AMS copolymers due to the higher termination rate constant compared with styrene and the strong chain-transfer effect of AMS oligomers and its monomer impurities. AMS-based materials are also yellower than their styrene counterparts.

By utilizing the difference, versus styrene, in reactivity ratio with acrylonitrile, a method for greatly increasing the production rate of AMS – AN copolymer has been developed [63]. Introducing low levels of styrene into the process to make an α-methylstyrene – acrylonitrile – styrene terpolymer is another way to increase reaction rates, with minor sacrifices in heat resistance.

4.2. Styrene – Methyl Methacrylate Copolymers

Methyl methacrylate readily polymerizes with styrene to form a styrene – methyl methacrylate copolymer [*25034-86-0*], SMMA, with similar physical properties to SAN, but with superior optical properties (low haze and glass-like appearance). Off-azeotrope copolymers are much easier to make, due to the similar reactivities of the monomers (Fig. 5). Commercial materials contain 20 – 60 % methyl methacrylate and are produced by methods similar to SAN [64, 65]. Methyl methacrylate is more commonly used to make clear ABS-type polymers (see Section 5.12.2).

4.3. Styrene – Maleic Anhydride Copolymers

Styrene and maleic anhydride react readily (Fig. 5) to give a copolymer [*9011-13-6*], SMA, with alternating monomer units. Reaction rates are significantly higher than for styrene alone or SAN, so polymerization conditions must be carefully chosen to control heat removal. Polystyrene technology is commonly used to produce thermoplastic SMA resins. The continuous stirred tank reactor technology permits synthesis of SMA copolymers with well defined S : MA ratio. The copolymerization parameters otherwise lead to the preferential formation of alternating copolymers.

The primary benefit of maleic anhydride is the greatly increased heat resistance. Also, the cost of this system is low, as both monomers are commodity materials. The products offer high rigidity, are commonly rubber modified, and are easily reinforced with fillers such as glass.

SMA resins generally fall into two categories. Low maleic anhydride ($<$ 25 wt %), high molecular mass thermoplastic materials are produced for molding or extrusion applications, low molecular mass materials with a high maleic anhydride content (25 – 50 wt %) are produced for alkali-soluble coatings and adhesives.

Thermoplastic SMA grades span a heat resistance range of 110 – 135 °C (Vicat softening point). Grades developed specifically for expandable foam applications and blends of SMA and polycarbonate for power tool housings are also available [66, 67].

For structurally demanding parts, rubber-modified SMA is reinforced with glass fiber (typically up to 20 %) by melt compounding. These materials are often used for interior automobile applications [67].

SMA resins are unstable at high temperature, liberating carbon dioxide. They must be adequately stabilized and processed at temperatures below 260 °C, otherwise splaying of parts results. The resin is stabilized by incorporating up to 1 % of a hindered phenol antioxidant with a thioester synergist.

4.4. Styrene – Maleimide Copolymers

For applications where heat resistance above the levels available from SMA resins is desirable, copolymers of styrene and maleimides can be used. These polymers are produced by copolymerizing styrene with a maleimide comonomer (e.g., *N*-phenylmaleimide) or by imidizing SMA with ammonia or an amine.

Polymerization of styrene and maleimides can be accomplished by any of the methods used for SAN. Imidization of SMA is achieved by injecting ammonia or an amine into a vented extruder, or by direct addition to the polymerization [66, 68].

SMI resins are used in a similar manner as SMA. They are rubber modified, glass reinforced, alloyed, or polymerized with termonomers such as acrylonitrile or acrylates. Unlike SMA, they are thermally stable at high temperatures and do not splay.

4.5. Styrene – Acrylate Copolymers

A recyclable, water-soluble copolymer of styrene and acrylate is available from Belland AG [69]. This copolymer contains carboxyl side groups which give it solubility in basic aqueous media. It is recoverable by precipitation via acidification. End uses include typical coatings applications for packaging laminates, book binding glues, and hygiene products.

5. Acrylonitrile – Butadiene – Styrene (ABS) Polymers

5.1. Definition and Structure

ABS [*9003-56-9*] and HIPS (Chap. 1) represent the industrially most important thermoplastic two-phase systems with an amorphous structure. The ABS polymers are based on three monomers: acrylonitrile (A), butadiene (B), and styrene (S). The polymer components have different chemical compositions and coexist as two separate phases whose compatibility is controlled by their structure and chemical microstructure.

In all classical ABS molding compounds the continuous phase (matrix) consists of copolymers of styrene (or an alkylstyrene) and acrylonitrile. An elastomer based on butadiene forms the disperse phase that is distributed in the continuous phase and has a characteristic morphology (Fig. 9).

ABS is mainly produced via two major industrial processes: Emulsion-ABS by compounding of emulsion-made rubbers into the SAN matrix; and solution-ABS via dissolving a rubber (commonly: butadiene homopolymer) in styrene – acrylonitrile and subsequent bulk polymerization, similar to the HIPS process (see Section 2.1). However, process combinations also exist.

Figure 9. ABS graft polymer showing rubber particles embedded in a styrene – acrylonitrile (SAN) copolymer matrix

Attempts to synthesize styrene-co-acrylonitrile-block-butadiene copolymers via living free radical polymerization have not resulted in commercial products so far [70].

5.1.1. Historical Aspects

The history of ABS polymers began in the mid-1940s. In attempts to produce bulletproof plastic sheets during the last years of World War II, polymer systems were developed from special butadiene – acrylonitrile copolymers and styrene – acrylonitrile copolymers with high molecular masses. These materials had a high impact resistance on account of their low thermoplastic flow, but could only be processed with extruders. Semifinished products (i.e., predominantly sheets, profiles, and pipes) were the first

molded parts to be made from ABS polymers and had dull or matt surfaces.

A drastic increase in the flow of the material allowed processing by injection molding and thus opened up the way for the production of engineering plastics. Improved processibility was obtained by the use of graft polymerization. This technique allowed the production of molded parts with glossy or high-gloss surfaces.

Systematic research into ABS polymers has led to the development of other multiphase plastics with a chemically different make-up. These contain other monomer units in addition to or as a replacement for acrylonitrile, butadiene, or styrene.

Recent developments include modifications of the A, B, and S monomer units as well as complex blend systems, in which the ABS polymers are components of polymer mixtures with an extremely wide range of properties. See also, → Polymer Blends.

5.1.2. Structural Principles

A knowledge of the structural principles of ABS polymers and the parameters on which they depend is required in order to understand production processes, their relationship to product properties, and the basis for the development of other ABS polymers.

The most important physical properties for the user are good thermoplastic flow, high rigidity, satisfactory heat resistance, high surface gloss (emulsion-ABS), and good (notched) impact strength down to temperatures as low as ca. − 40 °C.

Figure 10. Temperature dependence of the complex shear modulus of ABS graft polymer and its polymer components
a) SAN copolymer (matrix); b) ABS graft polymer; c) Polybutadiene (elastomeric graft base)

The simultaneous occurrence of high toughness and high rigidity results from proper bonding between the two polymer phases [71 – 78].

The elastic properties disappear on cooling to just above the glass transition temperature of the elastomer phase. The two-phase system then behaves as a brittle quasi-single-phase system.

The effect of the elastomer phase dispersed in the resin matrix is seen in plots of the modulus of elasticity as a function of temperature (Fig. 10) and of the stress – strain behavior at constant temperature (Fig. 11) [75, 76].

Figure 11. Stress – strain diagram for ABS graft polymer and its polymer components
a) SAN copolymer (matrix); b) ABS graft polymer; c) Polybutadiene (elastomeric graft base)

In Figure 11 the ABS polymer (b) absorbs significantly more energy during deformation up to the breaking point than the SAN resin (a). This is responsible for the high toughness of ABS polymers. The increased deformability in comparison with the pure SAN copolymer and the increased strain in comparison with the pure elastomer component (c) are due to yield processes,in which the applied energy causes the formation of wedge-shaped microcavities (crazes, Fig. 12 A) or initiates shear yielding of the matrix copolymer chains (Fig. 12 B). Both deformation processes are initiated by mechanical loading of the elastomer particles dispersed in the matrix.

The existence of more than one phase is therefore a prerequisite for high toughness. The deformation mechanisms and the effect of different elastomer particles and matrix parameters can be

investigated by electron microscopy techniques [79 – 84].

The glass transition temperature (T_g) depends on the stress frequency (it increases by ca. 30 – 40 °C after impact). The rubber used as the elastomer phase should therefore have as low a T_g as possible. Apart from special rubbers (e.g., silicone rubbers) polybutadiene is the most suitable. Polybutadiene (T_g – 85 °C) guarantees good low-temperature properties. Copolymers of butadiene with styrene (SBR) or with acrylonitrile (NBR) have much higher T_g values and are mainly used in special types of ABS.

Figure 12. Deformation mechanisms (schematic) in ABS polymers

Figure 13. Schematic structure of ABS graft polymers

Tough ABS resins require sufficient coupling between the elastomer particles and the resin matrix to ensure that forces can be transferred across the phase interfaces (phase coupling). Optimal phase coupling between the elastomer particles and the matrix is achieved by graft polymerization (Fig. 13). The graft shell surrounding the elastomer particles is synthesized (1) from the same monomers that are used to synthesize the matrix resin or (2) from monomers that produce a copolymer which is miscible (compatible) with the matrix.

Various polymerization processes (e.g., emulsion, solution, bulk suspension, and bulk processes) can be used to manufacture ABS molding compounds. These processes are described in detail elsewhere, → Polymerization Processes. The producer can also decide whether to use a single-step process involving reaction of polybutadiene and the styrene and acrylonitrile monomers (solution-ABS), or whether to produce the grafted polybutadiene and SAN separately (emulsion-ABS). The second route allows wider variation of individual parameters such as morphology of the elastomer phase (average particle size [85], and degree of cross-linking [75]). The styrene and acrylonitrile can also be copolymerized in different weight ratios [86], and the average molecular mass of the SAN copolymer modified as desired.

Styrene can be replaced partially or completely by α-methylstyrene (AMS). For special requirements (e.g., transparency or high heat resistance), terpolymers are also produced. Monomers used for this purpose, in addition to styrene and acrylonitrile, include methyl methacrylate, maleic anhydride, and *N*-phenylmaleimide.

5.1.3. Synthesis of the Two-Phase Structure

ABS polymers can be divided into ABS blend types and graft types.

In *ABS blend types*, a rubber copolymer is blended with a SAN copolymer. The rubber copolymer contains a matrix monomer (e.g., acrylonitrile in NBR rubber) or a monomer whose solubility parameters resemble those of the matrix [87 – 89]. These ABS systems have very little importance today.

Graft ABS polymers contain a polybutadiene graft copolymer as the elastomer component. The graft shell is constructed from the same monomer units as the resin matrix to give optimal phase interaction between the cross-linked rubber particles and the thermoplastic matrix [90, 91].

Grafting Reaction. The radical-initiated grafting of vinyl monomers (e.g., styrene, acrylonitrile, or methyl methacrylate) only produces satisfactory graft yields with a few rubbers. Industrially, butadiene polymers are used almost exclusively as the rubber (graft) base, polybutadiene being the most common because of its low glass transition temperature.

Grafting of vinyl monomers (e.g., styrene) on polybutadiene can take place by two mechanisms [74]:

1) Addition to the double bond

$$-CH_2-CH=CH-CH_2- + R^{\bullet} \longrightarrow -CH_2-\overset{\overset{R}{|}}{C}H-\overset{\bullet}{C}H-CH_2- \quad (1)$$

2) Abstraction of hydrogen.

$$-CH_2-CH=CH-CH_2 + R^{\bullet} \longrightarrow \quad (2)$$

$$RH + -\overset{\bullet}{C}H-CH=CH-CH_2- \rightleftharpoons -CH=CH-\overset{\bullet}{C}H-CH_2-$$

where R· is a polymer or initiator radical.

The polybutadiene radicals (R′ ·) formed according to Equation (1) or (2) react further with monomeric styrene to give the graft copolymer (3):

$$R'^{\bullet} + H_2C=\underset{\underset{C_6H_5}{|}}{CH} \longrightarrow R'-CH_2-\underset{\underset{C_6H_5}{|}}{\overset{\bullet}{C}H} \quad (3)$$

The allyl radical (Eq. 2) is not very reactive because of its high resonance stabilization. Its resonance energy is comparable with that of a styrene radical [92, 93]. Common polybutadiene rubbers are composed of 1,4-*cis*, 1,4-*trans* and 1,2-vinyl units. Grafting occurs mostly via abstraction of the allylic hydrogen atom of the 1,2-vinyl group.

Recently a copolymerization mechanism has also been proposed for the grafting reaction [94, 95].

The kinetics of the radical grafting reaction largely correspond to the normal kinetics of radical polymerization. At low rubber concentrations deviations occur because of cross-linking reactions. Grafting cannot be carried out with 2,2′-azobisisobutyronitrile as an initiator. The resonance stabilization of the $(CH_3)_2(CN)C\cdot$ radical prevents H-abstraction from the rubber backbone [96]. In the thermally initiated grafting of styrene onto polybutadiene the graft yield increases with increasing temperature and with the 1,2-vinyl group content of the graft base [97].

The degree of grafting can be varied within wide limits by factors such as the choice of polymerization process, the graft base : monomer ratio, the degree of conversion, the activating and regulating systems, and the use of redox initiators based on organic peroxides [98].

Cross-Linking of the Rubber Phase. The high hardness and toughness of ABS polymers requires controlled cross-linking of the rubber phase. If cross-linking is insufficient, the rubber particles dispersed in the SAN matrix (particle size ca. 100 – 1000 nm) are destroyed by the action of shear forces during processing. Rubber which is not cross-linked has no elasticity. The rubber may be cross-linked during the production of the graft base (emulsion polymerization), during the grafting reaction, or in the subsequent workup (bulk polymerization). The swelling index in a good solvent is usually used as a measure of the degree of cross-linking [99]. Quantitative relationships between the degree of swelling and the cross-linking density have also been established [100].

5.1.4. Properties of the Resin Matrix

The resin matrix of ABS polymers is mainly responsible for properties such as processibility and heat resistance of the molding compounds produced from it. Processibility depends predominantly on molecular mass and molecular mass distribution, whereas heat resistance is mainly determined by the chemical composition (i.e., the monomer units and their arrangement in the polymer chain) and the resulting glass transition temperature.

Table 7 summarizes the important properties of ABS matrix components.

Table 7. Properties of ABS matrix resins

Matrix component	Chemical construction	T_g, °C	Concentrations in the ABS blend, wt %	Heat resistance (Vicat B 120), °C	Other properties
SAN	random copolymer S : AN 80 – 65 : 35 – 20	115	95 – 50	104	decrease in thermostability at high acrylonitrile contents
AMS – AN – S copolymer	random copolymer AMS : S : AN 45 : 35 : 20		95 – 50	108 110	
AMS – AN copolymer	random copolymer AMS : AN ca. 70 : 30	128	95 – 50	117	depolymerization begins at 280 °C
AMS – AN sequence polymer	AMS : AN ca. 70 : 30 high proportion of AMS pairs	140	95 – 50	∼ 130	toughness lower than with random copolymers
Styrene – AN – NPMI terpolymer	random terpolymer S : AN : NPMI ca. 67 : 28 : 5	140	95 – 80	∼ 130	
Styrene – AN – MA terpolymer					high reactivity of the anhydride ring, heat resistance limited

AN = acrylonitrile; AMS = α-methylstyrene; MA = maleic anhydride; NPMI = *N*-phenylmaleimide; S = styrene

Styrene – Acrylonitrile (SAN) Copolymers. See also Chapter 2. Styrene – acrylonitrile copolymer resins with an acrylonitrile content of ca. 20 – 35 wt % are usually used for ABS polymers. The weight-average molecular masses are in the range ca. 50 000 to 180 000; the molecular nonuniformities $U = (\overline{M}_w/\overline{M}_n) - 1$ are ≥ 2 (for emulsion polymers) and between 1 and 2 (for bulk and suspension polymers); the glass transition temperature is ca. 115 °C. SAN resins can be synthesized by separate copolymerization or during graft polymerization. All ABS polymers also contain ungrafted SAN resin formed during graft polymerization.

α-Methylstyrene – Acrylonitrile (AMS – AN) Copolymers. See also Section 4.1. Copolymers of α-methylstyrene and acrylonitrile are closely related to SAN polymers. Their high glass transition temperatures and their chemical behavior, which is similar to that of SAN resins, yield ABS systems with improved heat resistance. Their thermostability decreases with increasing α-methylstyrene content (back cleavage of triads of α-methylstyrene units).

Resin production is carried out by emulsion [101], solution, or bulk polymerization [102]. Products usually have acrylonitrile contents of ca. 20 – 35 wt % with weight-average molecular masses of ca. 50 000 – 150 000.

Special copolymers with a high proportion of α-methylstyrene-containing sequences can be produced by emulsion polymerization and yield ABS polymers with high heat resistance (Vicat B temperature) of up to ca. 130 °C [103].

Other Vinyl Polymers. Copolymers of styrene and methyl methacrylate are used in transparent ABS. 4-Methylstyrene – acrylonitrile copolymers [104], styrene – maleic anhydride copolymers (Section 4.3), polyglutarimides [105], and *N*-phenylmaleimide – styrene – acrylonitrile terpolymers [106] are used for the production of systems that are analogous to ABS but with high heat resistances.

5.2. Structure – Property Relationships

The individual components described in Sections 5.1.3 and 5.1.4 can be used to draw up structure – property relationships for ABS polymers which, in turn, can be employed to predict properties from a small amount of basic data. The physical behavior of ABS polymers is partially based on the properties of the matrix and the rubber component.

The room-temperature toughness of ABS polymers generally passes through a maximum as the proportion of the rubber phase increases (Fig. 14). In parallel to this the modulus of elasticity, heat resistance, and flow properties decrease [107]. The low-temperature toughness behaves analogously to the room-temperature toughness; its absolute value, however, is determined by the glass transition temperature of the rubber component. Polymer properties are related to the acrylonitrile content of the resin matrix in the range relevant to industry (i.e., ca. 20 – 35 wt % acrylonitrile). Increasing the acrylonitrile content slightly improves chemical resistance and toughness (maximum at 34 %) but flow properties deteriorate [108].

Figure 14. Variation of the toughness of ABS with content of the elastomer (polybutadiene) phase

The most important structural parameters for a given matrix resin and rubber and a constant proportion of the rubber phase are the molecular mass and molecular mass distribution of the matrix resin and the structure of the grafted rubber, especially the particle size, particle size distribution, and degree of grafting and cross-linking.

An increase in the molecular mass of the matrix resin results in an increase in toughness and chemical resistance (environmental stress cracking) but simultaneous deterioration in the thermoplastic flow properties [109]. Broadening of the molecular mass distribution results in easier flow.

The use of cross-linked matrix resins in ABS polymers leads to embrittlement. Even a low degree of cross-linking is detectable because it lowers the surface gloss of molded products.

The properties of ABS polymers are most strongly influenced by the characteristics of the grafted rubber components. Toughness increases with particle diameter.

Grafted rubbers with average particle diameters below ca. 150 nm and a narrow particle size distribution lead to ABS systems which are brittle when subjected to high-velocity impact. In the particle size range of ca. 200 – 300 nm, the toughening effect of the grafted rubber is very strongly dependent on the degree of cross-linking and the cross-linking structure of the rubber base. A good toughening effect can also be achieved with relatively small particles if the rubber is weakly cross-linked. At particle sizes exceeding 300 nm, grafted rubbers with high toughness are generally obtained. However, with very large, compact particles (emulsion polymers with average particle sizes $\geq$ ca. 450 nm) toughness may decrease due to insufficient coupling to the matrix.

ABS molding compounds produced by bulk polymerization (particle size ca. 1 – 10 µm) generally have enhanced toughness because of their high proportion of grafting and matrix inclusion within the rubber phase (rubber phase volume).

Thermoplastic flow properties and the surface gloss of ABS polymers are also strongly dependent on the grafted rubber. Increasing particle size for a given rubber content (i.e., smaller number of particles) improves processibility [110], but leads to loss of surface gloss as a result of light scattering [111].

The degree of grafting, the graft density, and the length of the grafted chains of the grafted rubber also affect the properties of the ABS polymers [112]. An increasing degree of grafting improves coupling to the resin matrix resulting in a more uniform distribution within the matrix and a higher toughness. Grafted rubbers with a low degree of grafting tend to agglomerate so that the properties of the molded articles depend increasingly on processing conditions.

At a fixed degree of grafting, the length of the grafted chain and thus the graft density can be varied. Low graft density corresponds to a small number of very long grafted chains and a high graft density to very many short chains. A fine balance during the grafting reaction allows adjustment of the special requirements of ABS molding compounds (e.g., high toughness, improved flow properties).

5.3. Production of ABS Polymers

ABS can be produced by emulsion polymerization, bulk polymerization, or combined processes (Fig. 15).

There are two main types of *emulsion polymerization* which yield ABS graft rubbers with a rubber content of 5 – 85 wt %.

1) Separate production of the ABS graft rubber and SAN matrix with a subsequent mixing and compounding step

Figure 15. Overview of ABS production processes
A) Emulsion polymerization; B) Bulk polymerization

2) Total emulsion process, i.e., production of the molding compound containing both the grafted rubber and the SAN matrix by emulsion polymerization (the synthesis of a polybutadiene base precedes the ABS grafted polymer production)

Bulk polymerization starts from a separately produced rubber base (BR or SB solution rubbers). The compound is produced in a bulk process run continuously over several stages. Rubber content is limited to ≤ 20 wt % for viscosity reasons.

The *combined processes* include, e.g., the addition of emulsion graft rubber to bulk ABS molding compounds

The separate production of the grafted rubber and the SAN matrix has the advantage that the properties of each component can be controlled independently and different production processes can be used for the grafted rubber phase and the SAN matrix. SAN matrix copolymers are produced almost exclusively by thermally or radically initiated bulk polymerization [113, 114]. The two-stage bulk suspension process is also still used.

Other styrene copolymers besides SAN can also be combined with the ABS graft rubber (see Section 5.1.4). α-Methylstyrene – acrylonitrile (AMS – AN) copolymers or styrene – acrylonitrile – *N*-phenylmaleimide terpolymers, for example, give products with a high heat resistance because of their high glass transition temperatures [115, 116]. Some copolymers are only accessible via the separate bulk polymerization route [117]. Bulk or emulsion polymerization is used for AMS – AN copolymers [118, 119]. The bulk process has the advantage of an inherent degassing stage, so that products with very low residual monomer contents and thus high heat resistance can be obtained. However, yields and molecular masses are limited. The advantages of the bulk process lie in the fact that completely continuous processing is possible and that the grafted rubber particles are formed in situ, i.e., at the same time as SAN polymerization. The proportion of internal grafting is thus higher [120, 121] and products have a more favorable notched impact strength – hardness relationship than those produced by emulsion polymerization. The bulk ABS process includes a degassing step which means that unreacted monomers can be directly recycled.

5.3.1. ABS Production by Emulsion Polymerization

The emulsion process is the standard ABS production process but the principle of this method has also been applied to other rubber-modified, two-phase styrene copolymer systems [122 – 124].

The production of grafted rubbers with high rubber contents and their mixing with a separately produced SAN matrix is used worldwide.

The total emulsion process is of minor importance and is not described here.

The production of ABS grafted rubber consists of three stages:

1) Production of the graft base, i.e., a polybutadiene or butadiene copolymer latex with defined particle size, particle size distribution, and gel content
2) Grafting the styrene – acrylonitrile monomer mixture onto the graft base
3) Workup of the grafted rubber latex

The particle size, particle size distribution, and cross-linking density of the graft base; the degree of grafting; the proportion and morphology of the rubber-phase volume; and the molecular mass of the grafted SAN chains largely determine the properties of the resulting grafted rubber system. Bimodal ABS systems have optimal surface properties and toughness synergies. These systems are produced from a graft base with a bimodal particle size distribution, or from two grafted rubbers of differing particle size that are mixed at the latex stage and then worked up together. The particle size of ABS emulsion grafted rubbers lies in the range 50 – 600 nm, values of 100 – 400 nm being preferred. Figure 16 shows the production of uni- and bimodal ABS graft rubber systems.

Production of the Graft Base. The production of graft bases mostly takes place batchwise. The butadiene is polymerized at 5 – 75 °C and $\leq$12 bar. In the case of butadiene copolymers, the reactivities of the individual monomers must be taken into account. If compositions of the copolymers are chosen which lie outside the "azeotrope region" of the monomer mixture, then high chemical nonuniformity is avoided by using a continuous process and carrying out the polymerization until a given monomer conversion is reached. Unreacted butadiene is fed back into the first reactor of the reactor cascade.

Monomer – water weight ratios of 1 : 0.6 to 1 : 2 are used. Anionic emulsifiers are added in quantities of 1 – 5 parts per 100 parts of monomer to disperse the monomers and stabilize the polybutadiene latex particles. The alkali salts of disproportionated abietic acid or fatty acids, C_{12} – C_{18} *n*-alkyl- and *n*-alkylarylsulfonates are commonly used as emulsifiers. Emulsifiers are dosed such that the resulting latices have a surface tension of < 0.065 N/m and the particles are extensively coated with emulsifier. Emulsifier systems are preferred which are also used for the subsequent grafting reaction and which readily allow coagulation of the dispersed system on addition of acid or electrolytes to facilitate product isolation.

Polymerization is initiated with alkali peroxydisulfates or combinations of reducing agents with peroxydisulfates or organic (hydro)peroxides. The use of (hydro)peroxide systems allows a sufficiently high reaction rate at low temperature and modification of the polybutadiene microstructure [125].

The particle size can be controlled by varying the monomer – water ratio, by stepwise addition of emulsifier, and by adjusting the reaction temperature. A much more elegant method involves the use of seed latex technology, mostly in a semibatch process [126].

Polybutadiene bases with a bimodal particle-size distribution can also be produced by chemical or physical agglomeration of latex particles (Table 8). The advantage of this process lies in the fact that latices with a small particle size can be produced much faster than latices with a large particle size.

The molecular mass and cross-linking density of the polybutadiene bases are adjusted by means of modifiers (e.g., *n*-alkylthiols). Increasing quantities of modifier decrease the average polymer chain length.

Polymerization is usually terminated above 80 % conversion to ensure sufficient cross-linking of the rubber (gel contents > 60 %, preferably > 70 %). No shortstopping agents are used (apart from pure reducing agents) to prevent disruption of the subsequent grafting reaction.

The latex product is devolatilized to remove residual monomers by using vacuum and/or steam in a batch reaction, or continuously in a bubble column.

Grafted Rubber Production. A styrene – acrylonitrile monomer mixture is polymerized in the presence of the graft base. An increase in the ratio of monomers to polybutadiene is accompanied by increases in the net reaction rate, in the molecular masses of the grafted chains and of the "free" SAN copolymer, and in the

Figure 16. Composition of unimodal and bimodal ABS graft rubbers

Table 8. Production of bimodal ABS graft bases by agglomeration processes

Starting latex (particle size)	Emulsifier	Agglomeration process	Mean final particle size, nm	Reference
BR latex (100 nm)	alkylsulfonate	chemical agglomeration by addition of latices with hydrophilic groups	200 – 500	[127]
Butadiene – acrylonitrile copolymer latices (100 nm)	Na stearate	chemical agglomeration by addition of carboxylic acid anhydrides	200 – 400	[128]
BR latex (100 nm)	Na oleate, cannot be substituted	pressurized agglomeration using Manton – Gaulin homogenizer	200 – 800	[129]
Butadiene – styrene copolymer latex (50 nm)	alkali salts of abietic acid and fatty acids	chemical agglomeration	200	[130]
Butadiene – styrene copolymer latex, polybutadiene	alkali salts of fatty acids and abietic acid	agglomeration by freezing	200 – 400	[131]

degree of grafting. Since the reaction is exothermic ($\Delta H = -840$ kJ/kg), a monomer-feed process or a completely continuous process is used [132, 133]. If the copolymer compositions lie outside the azeotrope region of styrene and acrylonitrile, an increase in chemical nonuniformity is avoided by adding the more rapidly reacting monomer later (staggered dosing). The kinetics of the reaction are described by the Smith – Ewart theory, [134, 135]. Details of the grafting mechanism are given in [136 – 139].

The particle size, particle size distribution, and cross-linking density of the graft bases are directly related to the degree of grafting, graft density, rubber phase volume, and morphology of the grafted rubber [140]. The proportion of internal grafting generally increases with increasing particle size and decreasing cross-linking density of the rubber base. At constant particle size and rubber cross-linking density, the degree of grafting and the graft density become the factors determining the properties of the ABS product [77, 141]. The choice of initiator can influence the ratio of SAN copolymerization to graft reaction and the ratio of external to internal grafting. In comparison with monomer-soluble initiators, water-soluble peroxydisulfates lower the proportion of internal grafting and increase the proportion of free SAN copolymer [77].

The degree of grafting can also be affected by stepwise grafting whereby the formation of the graft shell determines the diffusion rate of the monomers [142].

If the weight ratio of monomers to graft base exceeds unity, molecular mass modifiers are usually added to the monomer mixture. They affect the graft reaction and the styrene – acrylonitrile copolymerization, the molecular masses of the

free and bound SAN chains, and the degree of grafting decrease.

The emulsifier systems used in the grafting reaction are usually the same as those used in the production of the graft base. High latex stability during the polymerization and ready coagulation during the product workup are also desired.

Stabilization and Workup of the Grafted Rubber. After completion of polymerization, excess (hydro)peroxide initiator is reduced with sodium hydroxymethanesulfinite. Stabilizers are added, generally in the form of a synergistically acting system, to protect the grafted rubber from oxidation during subsequent powder drying and compounding. The stabilizers usually comprise one or more phenolic antioxidants and a heat stabilizer. Long-chain alkyl thiodipropionates, long-chain alkyl phosphites, and low molecular SAN polymers with *S*-alkyl terminal groups are particularly effective [143 – 145]. The stabilizer systems should have a low volatility and must fulfil all ecological and toxicological legal requirements. To obtain a homogeneous distribution, the stabilizer system is added to the grafted rubber latex as an aqueous dispersion (0.2 – 1.5 parts by weight/100 parts of polymer) and coprecipitated with the grafted rubber after mixing.

To isolate the ABS graft rubber from the polymer latex, the emulsifier must be deactivated. Emulsifiers based on alkali carboxylates are coagulated and precipitated by adding dilute acid (acetic or mineral acid) to adjust the pH to below 3. Emulsifiers based on alkyl(aryl) sulfonates are coagulated by adding dilute aqueous solutions of inorganic electrolytes (e.g., $MgSO_4 \cdot 7\ H_2O$ or $CaCl_2$).

Strict control of the precipitation conditions is necessary to obtain a powder with a uniform particle structure and size distribution, from which all water-soluble polymerization and coagulation additives can be easily washed out. Coarse powder particles contain inclusions of precipitants which adversely effect drying and processing. Finely divided powders lead to filtration and wastewater problems. Powder structure, particle size, and particle size distribution can be affected by:

1) Consecutive or parallel addition of two or more grafted rubber latices and the precipitating agent [146]
2) The ratio of latex to precipitant solution
3) The temperature at which the precipitating agent and the grafted rubber latex are charged to the coagulation reactor or coagulation cascade
4) The type of stirring used to mix the process streams, the temperature control in the coagulation reactor cascade, and the average residence time

After coagulation the material is filtered with band, plane, or rotary filters and washed. The filter cake is then fed into a reslurry tank and mixed with fresh water. The slurry is processed in filter presses, extruders, or sieve centrifuges and the wastewater recycled to the process. The powder products have water contents of ca. 15 – 40 wt %. They are dried to moisture contents of < 1.0 wt % with two-stage paddle dryers, flow dryers, or vacuum tray dryers.

Alternatively, further processing of the moist grafted rubber can be performed in screw extrusion machines. In this case, dewatering leads to grafted rubber granulate [147] or, after mixing with a thermoplastic resin melt, to solid ABS products [148].

During the workup, measures are taken to lower the residual monomer content to comply with legal limits. Examples include latex degassing with a perforated plate column and countercurrent steam, the use of a precipitation – stripping process, and powder workup with a helical sieve followed by compacting and degassing in a twin-screw extruder [149, 150].

Production Process (Fig. 17). The first stage involves production of a polybutadiene latex with a defined particle size. An aqueous soap solution is formed in the polymerization reactor (a) at ca. 65 °C and the molecular mass modifier is added. After flushing with nitrogen, butadiene is pumped in and the polymerization is initiated with potassium peroxydisulfate solution. The reaction rate is determined by the heat removal capacity of the reactor. The maximum conversion rate is ca. 10 %/h. At conversions of ca. 80 – 90 % the reaction rate decreases; the monomer is then extensively consumed and cross-linking reactions begin. Polymerization is terminated by lowering the temperature to below 50 °C. Unconverted butadiene is vented and stirred out under vacuum.

In the second stage (the ABS graft rubber production process), the polybutadiene latex, an aqueous potassium persulfate solution, and part of the emulsifier solution are charged to the grafting reactor (d). The temperature is increased to ca. 60 °C and a styrene – acrylonitrile monomer mixture and the remainder of the emulsifier solution are charged to the reactor at a constant rate over 5 h. The reaction temperature is then increased to ca. 65 °C to complete polymerization (conversion $\geq$ 96 %, cycle time ca. 8 h, average reactor size is ca. 40 m^3). After running through the stabilization tank (h), the latex is coagulated. Washing and drying yield a powder which is subjected to a compounding step. After the addition of lubricants, dyes, and other additives, the polymer is pelletized (p).

5.3.2. Production of the Matrix Copolymer

The properties of the matrix copolymers are summarized in Section 5.1.4.

SAN Copolymers. The main ABS matrix components are styrene – acrylonitrile (SAN) copolymers with an acrylonitrile content of 20 – 35 wt % and a molecular mass in the range 50 000 – 180 000.

The production of SAN copolymers can take place by bulk, bulk suspension, or emulsion polymerization. In bulk polymerization the "azeotrope composition" is about 75 wt % styrene and 25 wt % acrylonitrile. In emulsion polymerization the quasi-azeotrope composition is 71.5 wt % styrene and 28.5 wt % acrylonitrile due to monomer partitioning [151].

Chemically and physically uniform SAN copolymers are obtained by *continuous bulk polymerization* (see also Section 2.1) [114, 152]. This also applies to compositions that lie outside the azeotrope region. Compared with suspension and emulsion polymerization, bulk polymerization has environmental advantages: production of wastewater is avoided and virtually all volatile components are removed from the product during workup. A disadvantage is, however, the fact that it is not possible to produce very high molecular masses due to high viscosities. Most of the matrix material is produced by this process.

Uniform SAN copolymers can also be obtained by *bulk suspension polymerization*, within the styrene – acrylonitrile azeotrope range [151]. A SAN prepolymer is first produced which is dispersed in water after addition of water-soluble dispersants and polymerized to give small beads [153]. Unreacted monomers are removed from the beads by means of steam or a

degassing extruder before or after the separation of the polymer – water mixture.

In *emulsion polymerization* (Fig. 17, f) the monomers are dispersed in water using an emulsifier. After addition of an activator dispersion, polymerization occurs to give latex particles (diameter ca. 50 – 200 nm). SAN production by emulsion polymerization is analogous to the production of ABS graft rubbers (see page 26) except that polybutadiene latex is not present.

Semibatch or continuous emulsion polymerization can be used to obtain product compositions with extensive chemical uniformity outside the azeotrope region. The semibatch process leads to molecular nonuniformities of ca. 1.5 – 2. In the continuous process the molecular nonuniformities are in the range 1.5 – 5 depending on the number of reactors and the average residence time. The emulsion-polymerized SAN copolymers show better flow properties and better resistance to stress cracking in the ABS blend compared with bulk-polymerized SAN. The toughness properties of bulk-polymerized SAN copolymers are not, however, achieved. The emulsion process always offers advantages if high molecular masses are desired [154]. The SAN emulsion copolymers are not usually isolated as such, but are mixed with the ABS grafted rubber latex in the latex step (Fig. 17, h). The mixture is then subjected to workup and residual monomer degassing to give an ABS powder blend.

α-Methylstyrene – Acrylonitrile (AMS – AN) Copolymers. ABS grades with a high heat resistance (HT-ABS) are produced by partial or complete exchange of the SAN matrix with compatible (AMS – AN) copolymers or α-methylstyrene – styrene – acrylonitrile terpolymers [155]. AMS – AN copolymers have a higher glass transition temperature and a higher heat resistance in the ABS blend. This system has an azeotropic mixture (69 wt % α-methylstyrene, 31 wt % acrylonitrile) [156].

Like SAN copolymers, AMS – AN copolymers can be produced by bulk and emulsion polymerization. The AMS – AN system has a much lower reaction rate, however, because of the small AMS growth-rate constant. The reaction rate cannot be increased by raising the temperature because depolymerization occurs [157, 158]. Two alternative approaches are used industrially:

1) A drastic increase in the acrylonitrile concentration of the monomer mixture in the starting phase of the reaction
2) Addition of styrene as a third monomer to give terpolymers with glass transition temperatures between those of SAN and AMS – AN copolymers [159]

The equipment requirements for the production of AMS – AN copolymers are similar to those for SAN bulk polymerization. However, higher average residence times are needed and thermal initiation is not possible. Multistep degassing is used to remove residual monomers and to achieve maximum heat resistance.

The most common route for the production of AMS – AN copolymers is semibatch emulsion polymerization. A high monomer purity ($\geq$ 99.5 %) is necessary. Long incubation times can be overcome by using seed latex technology [101]. Process conditions are similar to those of ABS graft rubber production (page 26). To achieve monomer conversions of $>$ 95 %, a pH of $\leq$ 6 must be maintained and an appropriate emulsifier chosen. More details on chemical composition are given in [160].

The emulsion copolymer is usually subjected to workup after latex mixing with ABS graft rubbers. A degassing step must be included between polymer workup and product compounding.

The glass transition temperature of the binary AMS – AN copolymer (ca. 128 °C) can be raised to 140 – 150 °C if the α-methylstyrene concentration at the beginning of emulsion copolymerization is raised above the azeotrope ratio and the reaction is terminated at conversions of $\leq$ 90 %. This increase is due to formation of sequence polymers containing AMS – AMS – AN blocks [161, 162]. The reaction rate and latex stability can be improved by using low concentrations of other monomers [163]. In the ABS blend these AMS – AN sequence polymers produce heat resistance (Vicat B 120) of 130 °C. Toughness diminishes slightly, however, because of incompatibility between the grafted rubber and the matrix.

ABS molding compounds with an AMS – AN matrix have less favorable flow properties than those with a SAN matrix. Although styrene can be replaced by α-methylstyrene in the ABS

graft rubber system, this has not been used industrially for processing reasons [164].

Styrene – Acrylonitrile – NPMI Terpolymers. Incorporation of imide comonomers into the SAN matrix yields heat-resistant ABS polymers [165, 166]. *N*-Phenylmaleimide (NPMI) has been used to produce styrene – NPMI – AN terpolymers [167]. Compare Section 5.3.3.

Other Styrene Copolymers. Attempts have been made to replace the SAN matrix by co- or terpolymers other than those described above. Although styrene can be copolymerized with almost all important vinyl monomers [168], none of the efforts made so far has been used industrially. Attempts to shift the heat distortion temperature of ABS polymers into the Vicat B region 120 – 130 °C by adding styrene – maleic anhydride co- and terpolymers failed because the anhydride ring opened under processing conditions [169, 170].

5.3.3. ABS Production by Bulk Polymerization

ABS production by bulk polymerization (Fig. 15 B) is based on the polymerization of styrene – acrylonitrile mixtures in the presence of a rubber substrate dissolved in this monomer phase. The process can be divided into three steps:

1) The rubber substrate is dissolved in the monomer mixture
2) The rubber – monomer mixture is prepolymerized with continuous mixing (conversion 15 – 30 wt %)
3) The polymer – monomer mixture is polymerized further by bulk suspension polymerization or by continuous bulk polymerization in a high-viscosity reactor cascade

Unlike the emulsion process (Section 5.3.1), no preformed rubber particles are present at the beginning of the grafting reaction. In emulsion polymerization the particle size distribution is determined by the particle size of the grafting base, in bulk polymerization it is mainly determined by the choice of the rubber base and the reaction conditions during prepolymerization and phase inversion. BR rubbers with a glass transition temperature of ≤ -80 °C are usually used as the grafting base. BR rubbers containing ca. 40 % of units with a 1,4-*cis* configuration are preferred because they do not crystallize and the resulting ABS blend has a good low-temperature toughness. The molecular mass and degree of branching are very important for adjusting the particle size and the rubber phase volume in the prepolymerization stage. Long-chain branched BR rubbers with an average molecular mass of 180 000 – 260 000 are commonly used [171]. High glass grades are made from star-branched BR rubbers with low solution viscosity. The rubber content is limited to ca. 20 wt % in ABS bulk processes for viscosity reasons.

The rubber is chopped to pieces and charged to a dissolving vessel. Dissolution in the monomer mixture and optionally a solvent (ethylbenzene, toluene and the like; usually 5 – 15 %) may take up to 10 h. Acrylonitrile acts as a precipitation agent for the butadiene rubber; with increasing acrylonitrile content of the solution less rubber can be dissolved and additional solvents are necessary. The rubber solution is transferred to a feed tank and continuously fed to the reactor cascade.

The prepolymerization stage is performed with continuous stirring. Phase separation and phase inversion begin during prepolymerization and largely determine the size, structure, and particle size distribution of the rubber phase in the resin matrix and thus the properties of the products. In the radical-initiated prepolymerization step, an oil-in-oil emulsion is formed at conversions of ca. 2 % [172 – 174]. Monomer-charged SAN droplets are emulsified in the rubber solution by graft SAN polymer chains which are simultaneously formed on the rubber. With increasing SAN formation the phase-volume ratio changes [175]. When the phase-volume ratio reaches unity, phase inversion begins and the rubber phase is then dispersed in the SAN phase [176], i.e., the SAN – styrene – acrylonitrile monomer phase becomes the continuous phase [177]. SAN is enclosed in the newly formed polybutadiene particles in the form of subinclusions. The phase inversion process, which is initially reversible, is terminated at conversions of ca. 12 – 15 %, depending on the rubber content of the starting solution.

The rubber particle size is determined by three main parameters:

1) The shear forces applied during stirring [178]
2) The viscosity ratio of the two phases [179]
3) The interfacial surface tension between the two phases [180]

Phase inversion can be detected by viscosity measurements. After phase inversion polymerization is continued to a conversion of ca. 25 – 30 %. The viscosity of the polymerizing mass is then already so high that the phase inversion becomes irreversible.

Another important factor affecting ABS production by bulk polymerization is the degree of grafting [181]. Grafting occurs as a result of hydrogen abstraction in the allyl position, grafting by copolymerization has also been discussed (Section 5.1.3) [93]. A first attempt to calculate the maximum possible degree of grafting as a function of conversion is described in [182]. The degree of grafting depends on the nature of the initiators and modifiers, as well as the different solubilities of styrene and acrylonitrile in the rubber and matrix phases [183]. This difference in solubility lowers the degree of grafting and leads to differing acrylonitrile contents in the grafted rubber and the matrix resin.

The molecular mass and molecular mass distribution are principally determined by process parameters (temperature, initiator concentration, solvent, and chain-transfer agents). Thiols are especially effective as molecular mass modifiers in the initial phase of polymerization, chain-transfer agents (e.g., terpinols) are only effective at higher conversions because of their smaller transfer constants.

Another important parameter is the establishment of defined rubber cross-linking densities. The rubber must be highly cross-linked to avoid crack formation within the particles on continuing "hardening out" of the system. If the rubber phase volume is known, the cross-linking density achieved in ABS polymers can be described quantitatively by a modified Flory – Rehner equation [100]. Since the cross-linking density is thermally controlled, this parameter is mainly determined in the degassing stage of the continuous bulk ABS process by variation of the temperature and the residence time [99, 184].

In the continuous bulk solution process, polymerization is carried out in a cascade of two or more reactors [185 186]. Solvents or mineral oils are often added to lower the viscosity and improve heat transfer.

Figure 18. Continuous stirred-tank reactor types [189]
A) Tower cascade; B) Stirred tank – tower combination; C) Ring disk; D) Continuous stirred-tank reactor; E) Stirred-tank cascade

Prepolymerization is performed in tower or stirred-tank reactors. Prepolymerization is followed by polymerization in a high-viscosity reactor or a tower reactor cascade [187]. Producers use specially constructed reactors for bulk solution polymerization (Fig. 18) mostly with laminar flow conditions [190]. The average residence times are ca. 10 – 15 h, and the reaction temperatures 170 – 270 °C [191]. Final conversions of 80 – 85 % are established. Various processes are used to separate the polymer and residual monomer at the end of the bulk poly-

merization stage: strand degassers, degassing extruders, thin-film evaporators, and spray evaporators. Common are two-stage processes involving a flash tank and a second facility.

The SAN matrix of ABS polymers usually has molecular masses in the range 50 000 – 170 000, the molecular nonuniformity $\overline{M}_w/\overline{M}_n$ is ca. 1.5 – 3.0. To achieve maximum toughening, an average rubber particle size of ca. 2.5 μm is aimed at. The particles generally have a cellular structure but other structures (e.g., capsules or lamellae) can be obtained by using polybutadiene or butadiene – styrene block copolymer bases or special phase and reaction conditions in the prepolymerization stage [192 – 194].

Bimodal or multimodal bulk ABS systems are being increasingly described [141, 195, 196]. There are two ways of producing them:

1) Two separately produced prepolymers with different particle sizes and graft structures are mixed with one another before charging to the bulk polymerization stage
2) Two polymers produced in separate prepolymerization and bulk polymerization stages are charged together to a workup zone

In 1990s, intensive research has been carried out on the production of bulk ABS products with a particle size of the rubber phase comparable to that of the emulsion rubber particles ($\leq$ 0.6 μm) [197] with the aim of producing lustrous moldings.

Common to all bulk ABS processes is the fact that the polymers are formed directly as pellets and are also sold in this form for certain uses. More demanding areas of use with defined color requirements need a subsequent compounding stage.

The bulk polymerization process is considered to be more economical than the emulsion and bulk suspension processes because of lower investment costs.

5.3.4. ABS Production by Bulk Suspension Polymerization

After prepolymerization, subsequent polymerization in the suspension process is carried out batchwise in cycles in two or more reactors.

Prepolymerization is started as a batch process. After the end of the phase inversion (conversion 25 – 30 %), the prepolymer is discharged from this reactor and is subjected to further polymerization in a second reactor or reactor cascade. Depending on the initiator system, the polymerization temperature is 80 – 120 °C [188] and the average residence time 2 – 4 h.

In the suspension stage the prepolymer is dispersed in the form of droplets (diameter ca. 0.1 – 1 mm) in an aqueous medium by means of intensive stirring. The water – prepolymer ratio is in the range 3 : 1 to 1 : 1. The suspension is stabilized by adding water-soluble organic polymers, e.g., poly(vinyl alcohol), or colloidal, water-insoluble compounds, e.g., calcium phosphate. Each droplet may be considered as a well-cooled bulk reactor. The bead size depends on the viscosity of the prepolymer syrup, the stirring conditions, the density difference between the organic and the aqueous phase, and the surface tension between the prepolymer syrup and the aqueous medium. The temperature is raised stepwise to 80 – 170 °C. "Oil-soluble" initiators are used. Since the necessary rubber cross-linking is only achieved at conversions of $\geq$80 %, it is important to adopt a definite temperature – time program. The average residence time of the suspension polymerization stage is ca. 10 h. The polymer dispersion is freed from unreacted monomer by the introduction of steam and transferred to a buffer tank. The polymer is separated from the aqueous phase in centrifuges; the polymer beads have a moisture content of $<$ 10 % and are dried with air in a rotating drier.

Production Process (Fig. 19). The BR or SBR rubber bales are cut into pellets (b) and charged to the dissolving vessel (c). The monomer – modifier mixture (a) is added.

The rubber – monomer mixture is transferred to the prepolymerization reactor (e), which is equipped for mixing highly viscous systems. After addition of the initiator, bulk solution polymerization is started by raising the temperature to ca. 90 °C. After ca. 8 h a conversion of ca. 20 – 30 % is reached. (The start of phase inversion is recognized by a sharp increase in the solution viscosity). After lowering the temperature to ca. 60 °C the peroxide initiators are added for the subsequent suspension stage. A ca. 20 % poly(vinyl alcohol) solution is often used as suspension agent (f).

The prepolymer syrup is heated to 120 °C and then pumped into the suspension polymerizer

Figure 19. Production of ABS by bulk suspension polymerization [186]
a) Monomer feed; b) Rubber chopper; c) Rubber dissolver; d) Solution storage; e) Prepolymerizer; f) Suspension makeup; g) Suspension polymerizer; h) Suspension buffer tank; i) Centrifuge; j) Dryer; k) Bead storage

(g). The ratios of aqueous phase to prepolymer syrup are chosen to give a solids concentration of ca. 40 %. After 3 – 4 h the temperature is raised to ca. 140 °C and maintained at that level for 3 – 4 h. At strongly decreasing monomer concentrations the required rubber cross-linking is thus obtained.

The resulting polymer suspension is led via a suspension buffer tank (h) into a sieve centrifuge (i) and separated. The aqueous phase is filtered and transferred to a water treatment plant. The polymer beads are dried in the presence of atmospheric oxygen (k) and then compounded.

5.3.5. Process Combinations

Producers have gone over to combining individual processes or process steps to exploit their advantages. Two possibilities are available:

1) The individual components are produced separately and worked up or compounded together
2) Different polymerization processes follow one another and are used to produce one product

Examples of the first alternative are:

1) An ABS polymer produced by emulsion polymerization is mixed (e.g., in a twin-screw extruder, with a SAN copolymer produced by bulk polymerization [198]).
2) ABS graft rubber is added to the workup stage of a continuous bulk SAN process [199].
3) An ABS polymer produced by bulk suspension polymerization is mixed in the compounding stage with ABS graft rubbers obtained by emulsion polymerization [200, 201]. This process can be used to obtain bimodal bigraft ABS systems [77, 202].

Examples of the second alternative include a latex suspension process (which is also used for high-impact polystyrene [203]) and a bulk dispersion process. Latex suspension polymerization can be performed batchwise or continuously, whereas the bulk dispersion process must be run continuously. Neither variant has achieved industrial importance so far. The bulk dispersion process combines the advantages of emulsion polymerization of a rubber base that has a defined particle size and particle size distribution with a bulk grafting step and a bulk SAN polymerization running parallel to it [204].

Like the bulk dispersion process, the latex suspension process starts from a rubber latex produced by emulsion polymerization. The latex is added to a styrene – acrylonitrile monomer mixture and the swollen mixture then converted into a monomer – polymer – water suspension by addition of dispersing and precipitating agents. Conventional bulk suspension polymerization then follows [205].

The main advantages of these two methods over the emulsion process are: there is no precipitation stage, wastewater contamination is reduced, larger particle sizes can be achieved more easily, and less polymerization auxiliaries are required. Advantages over the conventional bulk process are that the rubber chopping step and the production of a rubber solution are omitted. Because of the defined structure of the rubber particles, higher rubber contents can be used without incurring viscosity and heat removal problems. The critical phase inversion stage is circumvented and the process is reduced to a bulk process.

5.3.6. Additives [137]

See also, → Plastics, Additives.

Antioxidants. The rubber phase of ABS polymers is degraded by thermooxidation and light in the presence of atmospheric oxygen. Degradation is thought to proceed via a free-radical mechanism [206], resulting in yellowing, deterioration of mechanical properties, and embrittlement. Stabilizers or stabilizer systems are added at concentrations of 0.1 – 1 wt % to prevent degradation [207, 208] by scavenging radical intermediates or destroying hydroperoxides. They can be divided into sterically hindered phenols, organic compounds with divalent sulfur (thioethers) [143, 209], and organic compounds of trivalent phosphorus (phosphites) [207 – 210].

Light Stabilizers. ABS polymers undergo degradation reactions when exposed to UV light in the wavelength region 250 – 320 nm. They can be protected by UV absorbers, mainly derivatives of 2-hydroxyphenylbenzotriazole, 2-hydroxybenzophenone, and cinnamate esters. Hindered amine light stabilizers (HALS) [211] act by scavenging radicals produced during photooxidation [212].

Optimal protection can be attained by combining UV stabilizers and HALS compounds, generally at levels of ca. 0.2 – 1.5 %.

Lubricants. Long-chain alkyl compounds are often added to ABS polymers as lubricants to improve thermoplastic flow properties and facilitate removal of parts made by injection molding. Fatty acid esters, fatty acid amides, metal stearates (e.g., calcium stearate), or combinations of these substances are used at levels of ca. 0.5 – 2 %.

Antistatic Agents. Like all plastics of low polarity, ABS polymers tend to build up electrostatic charge on their surfaces which causes adverse effects such as static discharge or dust attraction. Polar antistatic agents are added at levels of 0.5 – 3 % to prevent this. They can be divided into cationic, anionic, or nonionic compounds [213, 214].

5.4. Quality Assurance and Standardization

Assurance of uniform quality is important both for the raw materials and the final products. A quality assurance scheme is shown in Figure 20. General guidelines on quality assurance, quality assurance programs, and quality audits are laid down in the EC standard EN 29 001 [215]. The test procedures include:

1) Chemical and physical analysis and methods of determination [216, 217]
2) Product-specific approval tests

Analytical procedures are based on appropriate DIN, ISO, and internal company or client-specific standards. They relate to monitoring of the production process and the final products.

Approval tests are based on the properties of the end product. They include mechanical properties (e.g., notched impact strength, hardness), thermal properties (e.g., heat distortion temperature), processing behavior (e.g., flow properties, dispersing), and fire behavior. They are carried out according to relevant national or international standards.

ABS plastics with an elastomer phase based on butadiene and that do not contain fibrous fillers are standardized according to ASTM D 1788–81, DIN 16 772 part 1, and ISO/DIS 2580–1. The large number of ABS types are classified in a grid system (cells), based on three or four properties, each with several ranges of values.

ASTM D 1788–81	
Izod impact strength at 23 °C (D 256)	6
Deflection temperature under load 264 psi (D 648)	6
Tensile stress at yield point (D 638)	6
Density (D 792)	1.0 – 1.2
Acrylonitrile content, %	min. 13 %
DIN 16 772 Parts 1 and 2 (Sept. 87, Dec. 88)	
Acrylonitrile content of the continuous phase	2
Vicat softening temperature VST B/50	4
Melt flow index, 220/10	4
Notched impact strength at 23 °C	5
ISO 2580–1 (1990)	
Acrylonitrile content of the continuous phase	2
Vicat softening temperature	4
Melt flow index, MFI 220/10	4
Notched impact strength at 23 °C	5
Modulus of elasticity from the bending test (ISO 178)	4

Testing: Product-specific properties
Release/rejection: Authorized by quality assurance department according to prescribed specifications and guidelines

5.5. Properties

ABS polymers have a high toughness (even in the cold), satisfactory rigidity, and good resistance to heat, chemicals, and environmental stress cracking. Molded articles with high dimensional stability and good surface quality can be produced by simple processing techniques. Although each of these properties can be bettered by other thermoplastics, no other system displays such a good combination of technically important properties.

A deeper knowledge of structure – property relationships [77, 218, 219] allows producers to supply a range of commercial products with user-oriented property profiles. Table 9 gives an overview of some commercial grades [220].

The properties of ABS polymers are determined by molecular and morphological parameters. The matrix composition and molecular mass, the type of rubber, the volume ratio of the rubber to the continuous phase, the rubber particle size, the grafted rubber structure, and the additive content are also important.

Standard ABS systems are opaque because their two phases have different refractive indices. Opacity depends on the particle size of the grafted rubber phase and the difference between the refractive indices of the two phases (Mie's theory) [221]. If the particle diameter is small enough compared with the wavelength of visible light, the two phases can be considered as optically homogeneous, and they appear translucent. Completely transparent systems are obtained if the refractive indices are equal. This is achieved, for example, by using a MABS resin matrix [222] or by completely substituting methyl methacrylate for acrylonitrile [223] (see also Section 5.12.2). In bimodal graft rubber systems, depending on ratio of the graft base to the grafted polymer, opacity may be observed despite equal refractive indices. The same applies if grafted rubber particles accumulate to form clusters during processing or tempering because of an incompletely closed graft shell.

In all ABS polymers the continuous phase (SAN and/or AMS – AN copolymer) is responsible for most of the chemical properties. Since only C–C bonds are present in the polymer chains, hydrolysis reactions are unimportant. ABS polymers are therefore generally resistant to aqueous solutions of salts, acids, or bases. They can absorb up to 1.5 wt % water on storage in aqueous media due to residual emulsifier and the polarity of the nitrile side groups. Under normal conditions, dimensional or property changes are negligible.

Table 9. Physical properties of various ABS types

Modulus of elasticity, N/mm^2	Yield stress, N/mm^2	Izod notched impact strength, kJ/m^2		Ball indentation hardness, N/mm^2	Vicat softening temperature, °C	Melt flow rate cm^3/10 min

Paraffinic hydrocarbons do not dissolve ABS polymers. A certain weight gain can be detected on storage in such media, and depends on the nature and quantity of the rubber phase. ABS polymers show equally good resistance to animal and vegetable fats and to a range of cosmetic creams.

Other organic liquids, such as halogenated hydrocarbons, aromatics, esters, and ketones dissolve the SAN phase. Oxidizing agents, especially inorganic acids, break up the chains and thus degrade the polymer. The resistance tables published by ABS producers only have limited meaning for practical applications. In order to answer specific questions, the running of a creep test under constant deformation, or, better, under constant tension is recommended. States of stress exist in each molded article as a result of its production. Additional stress is often produced by binding elements (e.g., rivets, screws, molded-in or enclosed metal parts) or on use of the article. Environmental stress cracking is low compared with polystyrene, but cannot always be excluded. Sensitivity towards stress cracking can be further lowered by increasing the acrylonitrile content and the molecular mass of the SAN phase, as well as by relaxation processes that are favored by the disperse rubber phase.

The double bonds in the elastic rubber phase (BR rubber) are responsible for the relatively high sensitivity of ABS polymers towards the long-term effects of heat, light, and weathering which result in yellowing and graying of the surface and a decrease in toughness [224]. Although satisfactory protection can be provided by using stabilizer combinations (phenolic antioxidant, a thiodipropionate ester, and/or a phosphite ester) during production and processing at 220 – 260 °C, long-term stabilization, particularly during simultaneous exposure to UV light and weathering, is difficult. Use of established stabilizer systems allows, however, repeated processing (e.g., recycling) without a serious decrease in toughness. For all indoor applications, ABS is aging-resistant. For outdoor use, adequate resistance to weathering is necessary. Three routes are currently used for this:

1) "Pigmenting" with soot (dark grey shades and black) to absorb UV radiation.

2) Coating semifinished or finished articles with barrier layers having a low oxygen permeability, with less sensitive materials, or with UV-protective paints.
3) Using grafted rubber systems with few or no double bonds. Although these systems do not contain the butadiene monomer unit they are nevertheless members of the ABS family because they have the same basic structure and morphology. They are SAN copolymers that are rendered impact-resistant by a dispersed elastomer phase.

At processing temperatures above 280 °C, ABS polymers lose their toughness because of damage of the rubber phase. Depolymerization begins above 300 °C. In the presence of atmospheric oxygen, decomposition can begin at ca. 280 °C.

5.6. Special Product Modifications

Heat-Resistant ABS Polymers. To increase heat resistance the SAN matrix is generally replaced totally or partially by an AMS – AN copolymer matrix. This is associated with small reductions in toughness, flow properties, and surface quality [225, 226]. To counteract these disadvantages, several methods are available to the producer:

1) Use of an AMS – AN sequence polymer matrix with an increased proportion of AMS – AMS – AN structural units (Vicat B values of ca. 130 °C can be reached) [161, 162]
2) Use of a matrix consisting of a styrene – acrylonitrile – *N*-phenylmaleimide terpolymer (Vicat B values of 130 °C)
3) Use of blends with polymers having higher heat resistance, e.g., polycarbonates or poly (butylene terephthalate) [227 – 229]

Commercial high-temperature ABS (HT-ABS) grades may either have good toughness with only a limited increase in the Vicat values or a limited toughness and Vicat values in the range 115 – 130 °C.

Glass-Fiber-Reinforced ABS Polymers. Reinforcement of ABS with 15 – 20 wt % glass fiber increases the modulus of elasticity by a factor of 2 – 2.5 [230]. The reinforced material has a lower thermal expansion coefficient (and thus high dimensional stability) as well as high rigidity, hardness, and heat resistance. Finished articles with smooth surfaces can then be obtained by appropriate coordination of the flow properties, glass fiber length, and glass fiber sizing material.

Flameproofed ABS Polymers. Standard ABS plastics are classified as flammable according to ASTM D 635 (rate of combustion 5 – 7 cm/min) and as class HB according to the UL 94 test. They also pass the Motor Vehicle Safety Standards (MVSS) test 302 and the so-called Kleinbrenner-Test (limited burning test) DIN 4102 B 2 (see also → Flame Retardants, Chap. 2). For certain applications addition of flame retardants is necessary (mostly halogen compounds in combination with antimony trioxide) to obtain UL 94 V-0 grades.

The brominated diphenyl ethers used in the past as flame retardants have been replaced by other compounds (e.g., brominated oligostyrenes and polycarbonates).

5.7. Legal Aspects

ABS polymers are subject to a large number of legal regulations during production, processing, use, and disposal. A few examples are given here and they relate to the situation in Germany. Similar regulations apply in other countries.

The monomer building blocks A, B, S, and AMS are classified as hazardous substances [231]. Contact with these monomers requires observance of maximum workplace concentrations. See also, → Acrylonitrile, Chap. 9; → Butadiene, Section 8.3; → Nitriles, Section 2.5; → Styrene.

Emissions of ABS production plants are controlled by clean air regulations (TA-Luft) and the law governing wastewater discharge (Abwasserabgabengesetz). Waste materials are subject to the waste disposal law (Abfallbeseitigungsgesetz).

In the processing of ABS pellets, traces of volatile components are formed, which may include residual monomers. As in ABS production, the maximum workplace concentrations must be observed.

Table 10. Product development of acrylonitrile based styrene copolymers (ABS, SAN, ASA, etc.) (10^3 t)

Region	1995	2000	2005
EU	650	800	800
NAFTA	700	800	800
Asia	2300	3400	4700
Others	200	250	300
Total	3850	5250	6600

Finished articles based on ABS polymers can be used in industry without limitation. EC guidelines govern toys and contact with foods [232]. Similar guidelines apply in other countries. These stipulate the monomers permitted for plastics production, polymerization auxiliaries, and additives. They also prescribe limiting values for the use of individual components and for their maximum transfer from the plastic into foods and food substitutes. The maximum proportion of heavy metals in pigments is an important criterion for toys [233].

In the area of disposal, restrictive legal measures are being prepared that prescribe recycling of used components (e.g., in the automotive and electrical sectors).

5.8. Storage and Transportation

ABS pellets can be stored and transported in polyethylene sacks stacked on pellets, in octatainers with polyethylene liners, in big bags, and also in silo containers. Labeling according to GefStoffV and EC guidelines is not necessary. Safety data sheets must be enclosed with the goods for road, rail, or marine transport. The surfaces of the pellets absorb water, which must be removed by predrying (e.g., 2 h at 70 °C) before processing.

ABS powders which are used as additives (e.g., for PVC) must be stored and transported in explosion-proof systems because of their ready oxidizability and large specific surface area. Measures should also be taken against buildup of electrostatic charge. The powders are stored and transported in polyethylene sacks or silo containers. If there is a danger of dust formation, dust masks must be worn.

5.9. Uses

ABS polymers are widely used as engineering materials [234 – 236]. The main consumers are the automotive industry, the domestic appliances industry, the data technology and telecommunications area, and producers of refrigeration equipment, toys, sports articles, and semifinished articles. ABS polymers have a very favorable price – performance ratio. In the automotive industry ABS often competes with modified polypropylenes, but in other applications it also replaces industrial thermoplastics and thermoplastic blends.

Trade names and producers of ABS polymers follow:

BASF	Terluran
Chi Mei	Polylac
Cheil	Starex
Dow Chemical	Magnum
Formosa Plastics	-
GE Plastics	Cycolac
Lanxess	Novodur
LG Chemicals	-
Techno Polymer	-
Toray Industries	Toyolac

5.10. Economic Aspects of Acrylonitrile-Based Styrene Copolymers

The different polymer production and sales options only permit the joint evaluation of data for all acrylonitrile-based styrene copolymers (ABS, SAN, ASA, AES, and ACS). The major part ($> 75\,\%$) is assignable to ABS.

Consumption of acrylonitrile-based styrene copolymers has grown considerably during the last years (Table 10) reflecting their wide use as engineering materials and blend components for other industrial thermoplastics. Nominal production capacities and producers are listed in Table 11. Consumption is estimated to grow by 5 – 6 % over the next years.

Table 11. Worldwide production capacities for acrylonitrile-based styrene copolymers in 2006 (10^6 t)

Company	Region	Capacity
Chi Mei	Asia	1.2
BASF	Asia, EU, NAFTA	0.9
LG Chem	Asia	0.75
Lanxess	Asia, EU, NAFTA	0.7
GE Plastics	Asia, EU, NAFTA	0.6
Formosa Chemicals	Asia	0.45
Cheil Industries	Asia	0.4
Dow Chemical	Asia, EU, NAFTA	0.4
Techno Polymer	Asia	0.3
Grand Pacific	Asia	0.25
Kumho	Asia	0.2
Jilin Chemical	Asia	0.2
others		1.2

5.11. Recycling

ABS articles can be recycled in two ways:

1) The used articles are returned and used directly in the production process (direct recycling)
2) They are degraded chemically into their individual components (i.e., acrylonitrile, butadiene, styrene) or other organic compounds which are then recycled (chemical recycling) [237]

Figure 21. ABS recycling operations
Impact strength of ASA, AES, and ABS

The interest of ABS producers and consumers is concentrated on the first method. Investigations carried out by raw materials producers and the automotive industry show that sorted ABS polymers are well suited to direct recycling (i.e., defined quantities of recycled material are added to the primary material) [238, 239]. Tests have shown that incorporation of 20 % and 50 % recycled ABS derived from articles sorted into pure grades has very little effect on (notched) impact strength, heat resistance (Vicat B 120), and the melt flow index [240]. The basic operations involved in ABS recycling are summarized in Figure 21.

5.12. ABS-Analogous Systems

ABS-analogous systems are elastomer-modified, two-phase thermoplastic systems with the same basic structure as ABS (i.e., a SAN-grafted rubber phase embedded in a SAN matrix). Production methods and principles are the same as those used as for ABS.

5.12.1. ASA, AES, and ACS Polymers

ASA, AES, and ACS polymers consist of acrylonitrile and styrene grafted onto acrylate, EPDM, or chlorinated polyethylene rubbers, respectively. In these polymers, aging resistance is increased by substituting the polybutadiene rubber of ABS by a rubber base which is only slightly or not at all susceptible to oxidation. Other features of ABS (e.g., toughness – hardness and toughness – heat resistance behavior or the coupling behavior of the grafted rubber) should be retained. These conditions can, however, only be partly satisfied because appropriate "saturated" elastomer candidates behave less favorably than butadiene polymers; they have a higher glass transition temperature and are less prone to grafting reactions. The SAN matrix itself does not have unlimited aging and weather resistance; SAN copolymers undergo oxidative degradation in the presence of air and this is independent of the degradation behavior of the grafted rubber system [241]. Addition of light stabilizers can delay, but not prevent degradation. To obtain rubber-modified, two-phase plastics that are completely aging- and

weather-resistant, another matrix system such as poly(methyl methacrylate) must be used.

Acrylate rubbers (ACM), ethylene – propene rubbers (EPM or EPDM) (→ Rubber, 3. Synthetic), chlorinated polyethylene, and other oxidation-resistant rubbers (e.g., silicone rubbers) have been suggested for the production of elastomer-modified, two-phase plastic systems [242, 243]. However, only the first three of these elastomers have been used in aging-resistant ABS polymers. Only ASA [244], AES [245], and ACS polymers are of industrial importance.

ASA production starts from a poly(butyl acrylate) rubber produced by emulsion polymerization and with a uni- or bimodal particle size distribution. To achieve a sufficiently high degree of grafting in the subsequent grafting stage, one of the following grafting bases is used:

1) A terpolymer from *n*-butyl acrylate, vinyl methyl ether, and butadiene [246]
2) An *n*-butyl acrylate – butadiene copolymer [247]
3) A copolymer consisting of butyl acrylate and a monomer acting as a cross-linking or grafting center [248]

Production and workup of ASA graft rubber obtained by emulsion polymerization require the same process parameters and reaction conditions as those described for ABS in Section 5.3.1.

Seed latex technology offers a further possibility, starting from a finely divided polybutadiene seed latex [249].

ASA products are obtained by compounding the grafted polymers and separately produced SAN copolymers with additives and colorants.

AES production usually starts with an EPDM rubber system with 7 – 12 double bonds for every 1000 carbon atoms [250]. At a rubber content of 10 – 50 % the AES and grafted rubber are produced by continuous bulk solution polymerization as described for ABS in Section 5.3.3 [251]. The rubber is dissolved in a monomer – solvent mixture and then charged to the first reactor of a bulk solution polymerization plant. The final product can be isolated analogously to ABS but a precipitation stripping process can also be used for grafted rubber systems with high EPDM contents.

ACS production is analogous to AES production, but is declining in importance.

Table 12 lists producers and trade names of ASA, AES, and ACS polymers.

ASA and AES polymers exhibit better aging behavior than ABS polymers (Fig. 22). The principal disadvantages of AES and ASA polymers compared with ABS polymers are their lower low-temperature toughness and lower heat resistance. Deeply colored modifications are difficult to produce (increased opacity due to the different refractive indices of the rubber base and the matrix).

Figure 22. Graft rubber systems after exposure to light (weatherometer test)

5.12.2. MBS and MABS Polymers

MBS polymers contain a methyl methacrylate (M) – styrene (S) copolymer matrix. The grafted rubber system embedded in the matrix consists of a methyl methacrylate – styrene copolymer shell grafted onto a polybutadiene or butadiene – styrene copolymer core. MABS polymers denote systems in which acrylonitrile is incorporated into the polymer matrix or the grafted rubber shell as an additional monomer. Table 13 lists producers and trade names of MBS and MABS polymers.

The composition of MBS and MABS polymers is usually chosen to ensure good transparency: the refractive indices of the matrix, the grafted rubber shell, and the rubber core should be the same; the grafted rubber particle diameter should be less than half the wavelength of visible light (i.e., < 200 nm).

Table 12. Producers and trade names of two-phase ASA, AES, and ACS plastics

Abbreviation	Matrix	Elastomer base	T_g of the elastomer base, °C	Producer	Trade name
ASA	SAN	acrylate rubber	ca. − 48	BASF	Luran S
				Lanxess	Centrex
				GE Plastics	Geloy
				Hitachi Chemicals	Vitax
				UMG ABS Ltd.	Dialac
AES	SAN	EPDM rubber	− 50 to − 60	Dow Chemical	Rovel
				Polimeri	Koblend
				Techno Polymer	AES
				Nippon A& L	Unibrite
ACS	SAN	chlorinated polyethylene	− 20 to − 30	Asahi Kasei	Stylac ACS

Table 13. Examples of producers and trade names of ABS, MBS, MABS, and MACR modifiers

Producer	Country	Product	Modifier for *	Trade name
BASF	Germany	ABS, MBS, MACR	PVC	Vinuran
Lanxess	Germany	ABS, MBS, MABS, MACR	PVC	Baymod
GE Plastics	United States	ABS, MABS	PVC, PC/PBT	Blendex
Rohm & Haas	United States	MBS, MABS	PVC, PC/PBT	Acryloid/Paraloid
Kaneka	Japan	MBS, MABS	PVC	Kane ACE
Mitsubishi Rayon	Japan	MBS, MABS	PVC, PBT	Metablen
Nippon A & L	Japan	ABS, MBS, MABS	PVC	Kralastic

* PBT = poly(butylene terephthalate); PC = polycarbonate; PETP = poly(ethylene terephthalate); PVC = poly(vinyl chloride).

MBS and MABS polymers are seldom used in the pure form; they are generally employed to modify other thermoplastics. They improve processing behavior, notched impact strength, and heat resistance of rigid poly(vinyl chloride) (PVC). The modifiers must be in powder form because rigid PVC is mostly processed as a powder. MBS and MABS polymers are therefore produced by emulsion polymerization or latex suspension polymerization.

MABS polymers used to modify PVC have the following requirements [252]:

1) The particle diameter of the grafted rubber must be < 200 nm to ensure high transparency [253]
2) To obtain transparent, colorless polymer blends, the composition of the modifier must be chosen such that its refractive index is the same as that of PVC ($n_D^{20} = 1.54$) [254, 255]
3) The modifier should have high activity at low dosage to minimize loss in modulus and heat resistance

A butadiene – styrene copolymer (weight ratio 75 : 25) is usually used as the rubber base to achieve a refractive index n_D^{20} of 1.54. Since methyl methacrylate is hydrolyzed relatively rapidly at alkaline pH [256], the grafting reaction is carried out at neutral or weakly acidic pH. Long-chain alkyl or arylsulfonates are used as emulsifiers and yield stable dispersions even below pH 7. Inorganic peroxides (e.g., potassium peroxydisulfate) and redox systems (e.g., cumene hydroperoxide and sodium hydroxymethane-sulfinite) are generally used as initiators [257]. The degree of grafting is controlled by adjusting the ratio of the grafted monomers to the rubber base and by the addition of molecular mass modifiers. The particle size of the grafted rubber is determined by that of the rubber base [120]. This, in turn, is controlled by the water – monomer ratio used in the polymerization, by the emulsifier concentration, or, in seed latex polymerization, by the particle size of the seed latex.

It is advantageous to carry out the grafting reaction in several stages [257, 258], or to use blends of grafted polymers which have a synergistic effect on the toughness of the PVC blend.

The grafted rubber and resin matrix can be synthesized separately and mixed in a workup [259] or compounding stage. Further workup and powder isolation are similar to those of ABS emulsion polymers. Like ABS polymers, MBS and MABS polymers must be protected from attack by atmospheric oxygen by the addition of stabilizers. MBS polymers are being increasingly used for modifying aromatic polyesters and polyester – polycarbonate blends [260, 261]. Since the processing temperature

Table 14. Overview of ABS blends

Grafted rubber	Matrix component I	Matrix component II	Phase ratio grafted rubber to matrix I/matrix II	Advantages	Uses
ABS	SAN [a] AMS – AN [c]	BPA – PC [b]	0.05 – 0.8/0.95 – 0.2	higher heat resistance, higher toughness than ABS, better processibility and environmental stress cracking behavior than PC	interior car fittings, housings for electronic instruments
ABS	SAN	PBT or PBT – PC [d]	0.25 – 0.45/0.75 – 0.55	higher toughness, higher low-temperature toughness than PBT or PC – PBT	car bumpers, housings
ABS		PVC [e]	0.05 – 0.5/0.95 – 0.55	higher toughness, higher heat resistance, better processibility than PVC, better flame resistance than ABS	containers, housings
ABS	AMS – AN	PVC			
ABS	SAN	PVC			
ABS	SAN	PUR [f]	0.05 – 0.25	higher low-temperature toughness, higher rigidity than PUR	ski boots, other injection-molded articles
ABS (modif.) [g]	SAN	PA 6, PA 66	0.05 – 0.4 0.95 – 0.6	higher toughness, better dimensional stability than PA, or PA 66	car parts

[a] SAN: Styrene – acrylonitrile copolymer, weight ratio S : AN 0.9 – 0.6/0.1 – 0.4;
[b] BPA – PC: Polycarbonate based on bisphenol A (BPA);
[c] AMS – AN: α-Methylstyrene – acrylonitrile copolymer in weight ratio AMS : AN 0.90 – 0.65/0.10 – 0.35;
[d] PBT – PC: Blend of poly(butylene terephthalate) and BPA polycarbonate in weight ratio 0.9 – 0.3/0.1 – 0.7;
[e] PVC: Rigid PVC, i.e., without addition of plasticizer;
[f] TPU: Thermoplastic polyurethane elastomer, preferably based on methylene diphenylene diisocyanate;
[g] ABS modif.: Incorporation of functional groups into the graft shell to achieve coupling to the amide group.

exceeds 280 °C, MACR polymer modifiers are used in which the SBR base is replaced by an acrylate rubber base (see also Table 13). Production requirements for MACR polymers are the same as for ASA and MBS graft rubber systems [262].

5.13. ABS Blends

Polymeric materials with novel properties can be obtained by the combination of known polymers in blends (alloys). Table 14 summarizes ABS-containing polymer blends. See also → Polymer Blends, Section 4.3.

Mixtures of ABS with polycarbonate (PC), poly(butylene terephthalate) (PBT), PBT – polycarbonate (PC), PVC, polyamide and thermoplastic polyurethane (TPU) are industrially important, both with regard to quantity and properties [263 – 265]. Other blends not mentioned in Table 14, (e.g., ABS – PETP and ABS – polysulfone blends) have not yet become important [266]. Blending of polycarbonate with ABS improves heat resistance, processing behavior, low-temperature toughness, and leads to synergistic effects [267, 268].

The combination of ABS – polycarbonate blends with triphenyl phosphate as a flame retardant and polytetrafluoroethylene as an antidripping agent yields molding compounds with a low flammability (UL 94 V-0) that are highly suited as housing materials.

ABS – polycarbonate and ASA – polycarbonate blends are predicted to have growth rates of 7 – 8 % in the next years.

The use of plastics for external automotive parts makes certain demands concerning heat resistance, low-temperature toughness (no spall fracturing), resistance to gasoline, and rigidity. Rubber-modified polymer blends have been developed as a solution to these problems. ABS, PBT, and ABS – PBT – PC blends are widely used. The addition of ABS graft rubbers to PBT improves impact properties [269].

The addition of 5 – 20 wt % of ABS graft rubbers to PVC increases its toughness and thus its possible uses. Opaque and transparent blends can be made depending on the size of the grafted rubber particles. The ABS modifier also improves processing behavior, particularly in the production of calendered films [270].

Addition of heat-resistant ABS polymers to rigid PVC (exchange of the SAN matrix for an AMS – AN or styrene – acrylonitrile – NPMI copolymer) increases the Vicat softening temperature and improves toughness. The addition of PVC to ABS polymers improves their

flammability behavior and, in combination with antimony trioxide, gives UL 94 V-0 materials. These blends are used on a large scale in the United States, Japan, and the Pacific Rim.

Crashpad sheets are used for covering car dashboards. They contain an ABS – PVC blend as the main component and their flexibility can be altered by extending the blend system with NBR (butadiene – acrylonitrile copolymer) or other polymer plasticizers.

The addition of ABS graft rubbers to thermoplastic polyurethanes in an in-situ reaction [271] can improve their rigidity and low-temperature toughness. Blends of this type (trade name Cycoloy, GE Plastics or Desmopan, Bayer) are widely used in ski boots. Addition of soft TPU types to ABS polymers allows wide variation of low-temperature toughness and processing behavior [272].

Polyamide 6 and polyamide 66 do not exhibit sufficient compatibility with standard ABS grades. This can be overcome by incorporating functional groups (preferably –COOH groups) into the shell of the ABS graft rubber system or using compatibilizing agents [e.g., imidized poly(methyl methacrylate) [273], or maleic anhydride copolymers [274].

ABS polymers and all other thermoplastics mentioned in Table 14 are produced as powders or pellets. Compounding can be carried out in two ways, usually in internal kneaders or twin-screw extruders [275]:

1) Powder mixing with subsequent melt compounding
2) Direct melt compounding in which the individual components are charged simultaneously or consecutively into the compounding equipment

Abstract

The article contains sections titled:

1. Introduction
2. Basic Reactions
3. Starting Materials
3.1. Polyisocyanates
3.1.1. Aromatic Polyisocyanates
3.1.2. Aliphatic Polyisocyanates
3.1.3. Blocked Isocyanates
3.2. Polyols
3.2.1. Polyether Polyols
3.2.2. Polyester Polyols
3.2.3. Polycarbonate Polyols
3.2.4. Other Polyols
3.3. Diamines and Amino-Terminated Polyethers
3.4. Special Building Blocks
3.5. Catalysts and Additives
4. Structure and Morphology
4.1. Polyurethanes Without Segmented Structure
4.2. Polyurethanes with Segmented Structure
4.2.1. Hard and Soft Segments
4.2.2. Segregation and Morphology
4.3. Cross-linking of Polyurethane

4.4. Polyisocyanurates
5. Production of Polyurethanes
5.1. Stoichiometry
5.2. Reaction without Solvents
5.2.1. One-Shot Process
5.2.2. Prepolymer Processes
5.3. Reaction in Solvents
5.3.1. One-Component Systems
5.3.2. Two-Component Systems
5.4. Reactive One-Pack Systems
5.5. Other Processes
6. Processing of Polyurethanes
6.1. Supply, Storage, and Preparation of Raw Materials
6.2. Metering and Mixing Technology
6.3. Processing Plants
7. Foams
7.1. Flexible Foams
7.1.1. Flexible Slabstock Foam
7.1.1.1. Raw Materials
7.1.1.2. Production
7.1.1.3. Properties
7.1.1.4. Trimming and Processing
7.1.1.5. Applications
7.1.2. Molded Flexible Foam
7.1.2.1. Production
7.1.2.2. Molding Process
7.1.2.3. Properties
7.1.2.4. Applications
7.2. Semirigid Foams
7.2.1. Applications
7.2.2. Production
7.2.3. Properties
7.3. Rigid Foams
7.3.1. Raw Materials

1. Introduction

Wolfgang Friederichs

Polyurethane (PUR) is the collective name for an extensive group of polymers with very different compositions and correspondingly varied property profiles. All PURs are built on a common principle: they are produced by the polyaddition process [1, 2] of (poly)isocyanates typically with (poly)alcohols. The characteristic chain link is the urethane group. In most cases two or more closely positioned urethane groups link poly(alkylene ether) and/or polyester sequences with molecular masses between ca. 200 and 6000 g/mol. Thus, the urethane group usually is only present to a minor extent.

PURs also include polymers produced from polyisocyanates that have urea, isocyanurate, or carbodiimide groups as their characteristic structural unit. As a result of the increasing importance of di- and polyamines and water as reactants, most of the industrially produced PURs contain urea groups (including the isocyanurates as cyclic ureas) as their main property-determining structural units.

A PUR is usually understood to be the fully reacted finished product (e.g., foams and coatings). These products are free from monomeric isocyanates, and unconsumed isocyanate groups, which may be present in small amounts, are bound to the PUR matrix. In adhesives and paints, the isocyanate-containing precursors are often called “PUR adhesive,” “PUR hardener,” or “PUR paint” to indicate the field of application of the end product produced from them.

The diisocyanate polyaddition process for synthesizing PURs is characterized by the following statements:

1. A large number of different reactants (monomers and oligomers) are available.
2. It is an exothermic reaction that can even take place at room temperature. No byproducts need be separated.
3. The reaction rate can be controlled over a wide range by catalysts, and in some cases a specific reaction can be accelerated by careful choice of the catalyst (e.g., tin compounds catalyze the urethane reaction, tertiary amines catalyze the isocyanate-water reaction; see Section Flexible Slabstock Foam).
4. Intermediates (prepolymers) with reactive end groups can be produced.
5. The stoichiometry influences the molecular mass (see Section Prepolymer Processes).
6. Production and composition can be adapted to various process techniques and extremely diverse product requirements.
7. A large number of end products can be made.

Besides their unique properties, one of the main advantages of PURs is that all types of articles (foams, elastomers, thermosets) can be produced starting from liquid reactive components. This has led to their great industrial importance (see Section One-Shot Process and Chap. Economic Aspects).

PUR products include highly elastic foams (mattresses, cushions, car seats), rigid foams (insulation materials); rigid and flexible moldings with compact skins (window frames, housings, skis, damping units such as car shock absorbers, front- and rear-end body parts, steering wheels, and shoe soles); engineering moldings with a high hardness and elasticity, ski boots, films, hoses, blow-molded parts, noise shields for trucks, seals for stoneware pipes, roller coatings, sealants, grouting compounds, surfacings for sport and play areas, off-road tires, windsurfing equipment, hydrocyclones, fenders, printing rollers, cable sheathing, catheters, high-quality paints, corrosion protection for steel-reinforced concrete, adhesives, textile coatings, high-gloss paper coatings, leather finishes, poromerics, glass fiber sizes, and wool finishing agents. The number and range of applications are constantly growing. The production, properties, technology, and use of PURs are reviewed in [3-13].

[Top of Page]

2. Basic Reactions [3, 4, 8]

Wolfgang Friederichs

The addition reaction of an alcohol to an isocyanate to give an urethane (carbamate) has been known since 1849 (WURTZ):

The extension of this reaction to di- and polyfunctional isocyanates and hydroxy compounds by OTTO BAYER in 1937 led to the principle of the polyaddition reaction resulting in the formation of linear, branched, or cross-linked polymers:

In addition to alcohols, the most important group of NCO-reactive compounds are the amines, which lead to the formation

of ureas:

Disubstituted urea

Trisubstituted urea

Ureas are also formed by the reaction of water with isocyanates, in which the carbamic acid formed in the first step of the reaction spontaneously decomposes to an amine with elimination of carbon dioxide. This amine then reacts with excess isocyanate to yield symmetrically substituted ureas:

Disubstituted urea

This reaction is the basic reaction leading to PUR foams, especially flexible foams.

Another process which leads to the formation of carbon dioxide is the reaction of isocyanates with organic acids. The reaction product formed in this way is an amide:

Amide

As the urethanes and ureas formed in the reaction mentioned above still contain reactive hydrogen atoms they can react with excess isocyanate to form allophanates and biurets, respectively.

Allophanate

Biuret

These cross-linking reactions are important in the production of PURs and play a key role in the development of polymeric materials with tailor-made properties.

Apart from these polyaddition reactions, the following reactions involving two or more isocyanate groups are also important in PUR chemistry (catalyst in parentheses):

Uretdione

Isocyanurate

Carbodiimide

Uretonimine

Due to the high reactivity of the isocyanate group some further reactions are well known but only of minor importance in the production of PURs. Examples are the reactions of amides and epoxides with isocyanates:

Acylurea

Oxazolidone

The tremendous number of different possible reactions not only play a role in the production of the final PUR polymers but also in the production of modified polyisocyanates (see Section Polyisocyanates) used as raw materials for PURs.

Usually the reactions described above proceed in parallel. For example, the production of foams is based on the combination of the NCO/ROH reaction leading to urethanes and the NCO/H_2O reaction leading to ureas and causing foaming of the reaction mixture by the evolution of carbon dioxide.

Other methods for preparing PURs which are usually not used in industrial applications are the polycondensation of bis-chloroformate esters and diamines, and the reaction of polyamines with carbonylbiscaprolactam (CBC) or polycyclocarbonates.

Thermally stable *N*-alkyl PURs are formed by the reaction of isocyanates with secondary diamines (e.g., piperazine). Since these products are unable to form hydrogen bonds, their properties are different from those of conventional PURs.

[Top of Page]

3. Starting Materials [3]

Wolfgang Friederichs

The range of PUR starting materials developed since the early 1950s is based on light petroleum fractions (ethylene, propene, naphtha). To a minor part renewable raw materials (natural products such as sugar, castor oil, etc.) are used [14-16]. The suitability of natural fatty acid esters [17, 18], lignin [19, 20], polysaccharides [19, 21, 22], and chitin as raw materials has been examined for special applications.

3.1. Polyisocyanates

See also ⟶ Isocyanates, Organic

More than 90 % of PURs are produced from aromatic polyisocyanates. Compared to aliphatic and cycloaliphatic polyisocyanates, the aromatic polyisocyanates show higher reactivities towards hydroxyl compounds and give PURs with better mechanical properties.

The aliphatic and cycloaliphatic polyisocyanates are used to obtain PURs that do not become discolored on exposure to light or heat. This is particularly important for coating materials (paints, varnishes, textile coatings, and glass-fiber sizes). The stability of aliphatic or cycloaliphatic polyisocyanates PURs can be improved by incorporating urea, biuret, or hydrazide groups into the polymer [23-25].

3.1.1. *Aromatic Polyisocyanates*

Aromatic polyisocyanates are primarily used for a wide variety of PUR foamed plastics, elastomers, thermosets, and adhesives.

2,4-Toluenediisocyanate [584-84-9] (TDI), 2,4-diisocyanatotoluene (**1a**), *bp* 121 °C (1.33 kPa), *mp* 21.8 °C.

1a

1b

Usually the pure 2,4 isomer or mixtures of 2,4-TDI (**1a**) with 2,6-TDI (**1b**) are used for industrial applications:

TDI 80 (80 % 2,4-TDI, 20 % 2,6-TDI), *bp* 121 °C (1.33 kPa) *mp* 13.5 °C, vapor pressure (25 °C) 3 Pa, equilibrium vapor concentration 30 ppm, MAK value 0.005 ppm (according to TRGS 900).

TDI 65 (65 % 2,4-, 35 % 2,6-), *bp* 121 °C (1.33 kPa), *mp* 5 °C.

1,3-Bis(3-isocyanato-4-methylphenyl)-2,4-di-oxo-1,3-diazetidine [26747-90-0] (**2**) (uretdione of 2,4-TDI, TDI-dimer; Desmodur TT, Bayer MaterialScience), *mp* 153 °C.

2

Uretdiones react as blocked isocyanates: the four-membered ring opens at elevated temperature to release the NCO groups.

"TDI-urea" [5206-52-0] (**3**) (TDIH, Bayer MaterialScience) *mp* 180–184 °C [26, 27]

3

1,3,5-Tris(3-isocyanato-4-methylphenyl)-2,4,6-trioxohexahydro-1,3,5-triazine [20649-21-6] (**4**) (TDI-trimer), ca. 51 % in butyl acetate (Desmodur IL, Bayer MaterialScience): NCO content ca. 8 %, viscosity (20 °C) 2000 ± 500 mPa · s.

4 (idealized)

Adduct of TDI and trimethylolpropane [21092-47-7] (**5**), 75 % solution in ethyl acetate (Desmodur L, Bayer MaterialScience): NCO content 13 ± 0.5 %, viscosity (20 °C) 2000 ± 500 mPa · s.

5

Monomeric MDI, 4,4′-Methylene diphenyl diisocyanate [101-68-8], 4,4′-methylene-bis(phenyl isocyanate), bis(4-isocyanatophenyl)methane, 4,4′-diisocyanatodiphenylmethane (**6a**), Monomer-MDI, *bp* 208 °C (1 kPa), *mp* 39.5 °C, vapor pressure (25 °C) <1 mPa, equilibrium vapor concentration 0.009 ppm, MAK value 0.005 ppm (according to TRGS 900)

6a

6b

60 % 2,4′-MDI (**6a**), 40 % 4,4′-MDI (**6b**) (Desmodur 1806, Bayer MaterialScience), *mp* 16–17 °C.

Polymeric MDIs (PMDIs) [9016-87-9] (**7**) typically contain 30–70 % dinuclear components (n = 0), 14–40 % trinuclear components (n = 1), and 15–30 % higher nuclear components (n > 1), viscosity 50–20000 mPa · s, NCO content 25–33 %.

7

Urethanized 4,4′-MDI [60440-22-4] (Desmodur PF, Bayer MaterialScience) *mp* 10–15 °C.

Carbodiimidized 4,4′-MDI [37353-55-2], *mp* 10–15 °C (Desmodur CD, Bayer MaterialScience; for carbodiimidization, see Chap. Basic Reactions).

1,5-Naphthalene diisocyanate (NDI) [3173-72-6], 1,5-diisocyanatonaphthalene (**8**), *mp* 127 °C (Desmodur 15, Bayer MaterialScience).

8

Tris(4-isocyanatophenyl)methane [2422-91-5] (**9**), 20 % solution in ethyl acetate, NCO content 7 ± 0.1 %, viscosity (20 °C) ca. 1 mPa · s.

9

Aromatic isocyanates with the NCO group in the benzylic position behave similarly to the (cyclo-)aliphatic isocyanates with regard to reactivity and light stability:

1,3-Bis(1-isocyanato-1-methylethyl)benzene [2778-42-9] (**10**), m-tetramethylxylylene diisocyanate (TMXDI, American Cyanamid) [28, 29], *mp*–10 °C, *bp* 150 °C (49.5 kPa).

10

3.1.2. *Aliphatic Polyisocyanates*

Aliphatic and cycloaliphatic polyisocyanates are used to obtain light-stable PURs. This is particularly important for coating materials (paints, varnishes, textile coatings, and glass-fiber sizes).

Hexamethylene diisocyanate (HDI) [822-06-0], 1,6-diisocyanatohexane (**11**) (Desmodur H, Bayer MaterialScience), *bp* 127 °C (1.33 kPa).

11

Biuret based on HDI, *N*-isocyanatohexylaminocarbonyl-*N*,*N′*-bis-(isocyanatohexyl) urea [28182-81-2] (**12**), biuret triisocyanate (technical mixture), ca. 75 % solution in methoxypropyl acetate/xylene (1/1) (Desmodur N75, Bayer MaterialScience), NCO content 16–17 %, viscosity (20 °C) 250 ± 100 mPa · s.

12 (idealized)

Trimer based on HDI, 2,4,6-trioxo-1,3,5-tris(6-isocyanatohexyl)hexahydro-1,3,5-triazine [28182-81-2] (**13**), trimeric hexane diisocyanate, ca. 90 % solution in butyl acetate (Desmodur N3390, Bayer MaterialScience), viscosity (25 °C) 2500 ± 500 mPa · s, NCO content 21.5 %, monomer content < 0.5 %.

13 (idealized)

Unsymmetrical trimer based on HDI, 2,4-dioxo-3,5-bis(6-isocyanatohexyl)-6-(6-isocyanatohexyl)hexahydro-1-oxa-3,5-diazine [28182-81-2] (**14**), unsymmetrical trimeric hexane diisocyanate [30] (Desmodur XP2410, Bayer MaterialScience), viscosity (23 °C) ca. 700 mPa · s, NCO content ca. 24 %, monomer content <0.3 %.

14 (idealized)

Isophorone diisocyanate (IPDI) [4098-71-9], 3,5,5,-trimethyl-1-isocyanato-3-isocyanatomethylcyclohexane (**15**) (IPDI, VEBA), *bp* 158 °C (1.33 kPa), 70 % cis, 30 % trans [31, 32]. For reactivity, see [33].

15

Uretdione of IPDI (Crelan TP.LS 2147) [34], *mp* 105–115 °C, ca. 15.4 % NCO.

Trimer based on IPDI, 2,4,6-trioxo-1,3,5-tris(5-isocyanato-1,3,3-trimethylcyclohexylmethyl)hexahydro-1,3,5-triazine [53880-05-0], ca. 70 % solution in xylene/methoxypropyl acetate (1/1) (Desmodur Z4470, Bayer MaterialScience), softening range 90–110 °C, NCO content 17 %, monomer content < 0.5 %.

1,1-Methylenebis(4-isocyanatocyclohexane), H12-MDI [5124-30-1], 4,4′-diisocyanatodicyclohexylmethane (**16**), trans,trans-4,4′-diisocyanatodicyclohexylmethane, *mp* 83 °C [35]. Technical isomer mixture (24 % *cis*,*cis*, 43 % *cis*,*trans*, 20 % *trans*,*trans*, 13 % 2,4 and 2,2′ isomers): *mp* 15 °C (Desmodur W, Bayer MaterialScience)

16

3.1.3. *Blocked Isocyanates [36-39]*

Polyisocyanates or prepolymers containing NCO groups are not stable on storage in the presence of atmospheric humidity or compounds that contain reactive hydrogen atoms.

Reaction of the NCO groups with certain organic compounds that have acidic hydrogen atoms such as phenol, cresol, nonylphenol, caprolactam, and methyl ethyl ketoxime leads to “blocked isocyanates,” which are stable (storable) at room temperature and labile at elevated temperatures. These adducts are inert to polyols at room temperature and can be mixed with them in one-pack systems. At higher temperatures, usually at 140–180 °C the blocking agent is released, and the free isocyanate reacts as usual with the NCO-reactive components. Due to their thermal lability, uretdiones and uretonimines also behave like blocked isocyanates.

For the physical blocking of solid polyisocyanates by a diffusion barrier layer, see Section Reactive One-Pack Systems.

3.2. Polyols

Polyols are the largest group of PUR starting materials. The wide range of properties of the resulting PURs is largely determined by the chemical composition and molecular mass of the polyols. The largest group of polyols used for PURs is the group of polyethers. The volume of polyesters is much smaller, but they nevertheless have become more important, especially for flame-retarded rigid foams (see Section Special Types).

3.2.1. *Polyether Polyols*

See also ⟶ Polyoxyalkylenes

Polyethers (polyether polyols) with terminal hydroxyl groups are produced by addition of cyclic ethers, especially propylene oxide (PO, R′ ═CH_3) and ethylene oxide (EO, R′ ═H), to polyfunctional “starter” molecules.

Usually, the EO and PO units can be structured as homo blocks, produced by batchwise addition of EO and PO to the starter molecule, or as mixed blocks by feeding an EO/PO mixture to the starter. The combination PO block-mixed block-EO block is common.

The structure determines the reactivity, the hydrophobic-hydrophilic properties, the surface activity, and consequently the foaming behavior of the polyethers. Polyols with terminal EO units contain primary hydroxyl groups and consequently have

a higher reactivity than polyols with the secondary hydroxyl groups of terminating PO units.

The following starters are typically used industrially: ethylene glycol (EG), 1,2-propanediol (PG), bisphenol A (BPA), trimethylolpropane (TMP), glycerol (GLY), pentaerythritol, sorbitol, sucrose, water, ethylenediamine (EDA), and diaminotoluene (TDA). Monofunctional polyethers are usually started with 1-butanol.

Depending on their structure, two groups of polyethers can be distinguished: long-chain polyols, mainly used for flexible foams, and short-chain polyols, mainly used for rigid foams.

The long-chain polyols typically have hydroxyl numbers below 100 mg KOH/g and functionalities of 2 to 3, which corresponds to molecular weights of 2000 g/mol or more. The properties of some long-chain polyols are given in Table 1.

Table 1. Properties of long-chain polyether polyols

Starter	Alkylene oxide	Functionality	M_r, g/mol	OH no., mg KOH/g	Viscosity (25°C), mPas
PG	PO/EO	2	4000	28	870
PG	PO	2	2000	56	310
TMP/PG	PO	2.8	3750	42	630
GLY	PO/EO	3	4800	35	860

The short chain polyols usually have OH numbers of 200 mg KOH/g or more, functionalities of up to 6, and molecular weights of 1000 g/mol or less (Table 2).

Table 2. Properties of short-chain polyether polyols

Starter	Alkylene oxide	Functionality	M_r	OH no., mg KOH/g	Viscosity (25°C), mPa s
TMP	PO	3	435	385	600
TMP	PO	3	305	550	1800
EDA	PO	4	350	620	19200
TDA	PO/EO	4	475	470	8000
Sucrose/PG	PO	3,1	385	450	15000

.

Polyethers produced from trifunctional starters and bifunctional cyclic ethers (e.g., epoxy resins) are highly branched and, to some extent, intramolecularly cross-linked [40]. Special polyethers contain, for example, quaternary ammonium or sulfonate groups [41, 42].

An important special polyether is polytetrahydrofuran [43], which is described in detail elsewhere (⟶ Polyoxyalkylenes). It is used mainly for the production of high-grade elastomers for the engineering field and is liquid above 40 °C [44, 45].

A newer process, known as the IMPACT process, uses double metal cyanides (DMC) as catalysts for the production of especially long chain polyether polyols [46-48] that show improved properties compared to polyols produced by the classical KOH process. During the addition of propylene oxide to the starter molecule, base-catalyzed isomerization of propylene oxide to allylic alcohol, which itself can act as starter molecule, leads to a mono-ol containing a double bond. These side products lower the average functionality of the polyols and reduce, for example, their stability against oxidation. The IMPACT process leads to polyols with extremely low mono-ol contents and therefore a low level of unsaturation and results in polyols with functionalities very close to the theoretical number. The IMPACT polyols have become more and more important, especially in the production of flexible foams.

Products based on polyethers have good low-temperature behavior and usually high hydrolytic stability. The viscosity of the liquid polyethers is relatively low (40–15000 mPa · s). A disadvantage of polyether polyols is that they undergo thermooxidative degradation on exposure to heat and atmospheric oxygen; UV radiation is mainly responsible for light-induced degradation changes. Both antioxidants and UV stabilizers counteract this degradation. In some special applications polyether polyols containing hydrazide or urea groups, both of which have a stabilizing effect, are used to avoid thermooxidative degradation.

Polyether dispersions (two-phase systems with a solid polymer as the disperse phase) are a further group of polyethers. Mainly styrene-acrylonitrile polymers (SAN polyols), polyurea, or poly(hydrazodicarbonamide) polymers (PHD polyols) are used as fillers. The dispersions are milky white, of higher viscosity than the corresponding base polyols, and completely stable to sedimentation. The average particle diameter is ca. 1 µm.

3.2.2. *Polyester Polyols*

Compared with polyethers, polyesters with terminal hydroxyl groups show outstanding resistance to light and thermal aging. PURs produced from them are therefore primarily used for paints, coating materials, and, due to their thermal

stability, for flame-retarded rigid foams. Special types are suitable for high-grade PUR elastomers [49, 50].

Polyesters are produced by polycondensation of di- and trifunctional polyols with dicarboxylic acids or their anhydrides. Polyols commonly used are ethylene glycol, 1,2-propanediol, 1,4-butanediol, 1,6-hexanediol, neopentyl glycol, diethylene glycol, glycerol, and trimethylolpropane. Common dicarboxylic acids or anhydrides are succinic acid, glutaric acid, adipic acid, phthalic anhydride, isophthalic acid, and terephthalic acid.

The hydrolytic stability of a polyester urethane is determined by the constitution of the polyester. Polyesters synthesized from glycols and dicarboxylic acids that each contain at least five carbon atoms have good hydrolytic stability. This is because the increase in hydrophobicity of the polyester segments repels moisture [49, 50]. The best results have been obtained with polyesters derived from 1,6-hexanediol and adipic acid.

Common polyesters based on adipic acid and ethylene glycol or ethylene glycol/1,4-butanediol provide inexpensive PUR elastomers of excellent quality. Their hydrolytic stability is lower than that of the polyesters mentioned above and can be considerably improved by appropriate stabilizers (see Section Catalysts and Additives).

Polyesters have a wide molecular mass distribution and, compared with polyethers, a high viscosity; many are glassy solids (polyphthalates) or crystalline (polyadipates). Polyesters containing diethylene glycol are ether esters; their viscosities are relatively low and their stability to hydrolysis and UV radiation is moderate. The average molecular mass of polyesters is 500–4000 g/mol. For properties, see Table 3.

Table 3. Properties of polyester polyols

Acid	Glycol	Functionality	M_r	OH no., mg KOH/g	Viscosity, mPas
Adipic acid	ethylene glycol	2	2000	56	500 – 600 (75° C)
Adipic acid	diethylene glycol/TMP	2.5	2300	60	900 – 1100 (75° C)
Phthalic anhydrid/adipic acid	ethylene glycol	2	1750	64	2200 – 3200 (75°C)
Phthalic anhydrid/adipic acid	diethylene glycol	2	560	200	6300 – 7600 (25°C)
Terephthalic acid	diethylene glycol	2	450	250	2700 – 7700 (25°C)

The polyesters always contain significant proportions of the monomeric glycol used in their synthesis, as well as short-chain oligomers and often nonfunctional cyclic esters. These substances can be removed for a limited time by thin-film distillation, but they are gradually reformed by transesterification.

3.2.3. *Polycarbonate Polyols*

Aliphatic carbonate esters (⟶ Polycarbonates) are produced by transesterification of dimethyl carbonate (DMC) or diphenyl carbonate (DPC) with glycols (e.g., 1,6-hexanediol).

Many investigations have been carried out on the production of polycarbonate by copolymerization of alkylene oxides with carbon dioxide [51-55], but this reaction is not used on an industrial scale as yet.

Polyaddition of caprolactone or pivalolactone to low molecular mass diols yields hydroxy-functional polylactones.

As the susceptibility of polyesters to hydrolysis increases with increasing dissociation constant of the acid on which they are based, the polycarbonates are highly stable against hydrolysis. In particular, polyester urethanes based on 1,6-hexanediol polycarbonate show an unmatched resistance to hydrolysis.

3.2.4. *Other Polyols*

Other oligomers and polymers with functional groups (OH, SH, COOH, NHR) can also be used for PUR synthesis (e.g., polythioethers, polyacetals, polyester amides, alkyd resins, and polysiloxanes).

Hydroxy-functional poly(1,3-butadienes) contain the hydroxyl function mainly in the terminal position as a result of polymerization with hydrogen peroxide. These compounds yield PURs with moderate mechanical properties but extremely high hydrolytic stability and good low-temperature behavior. Bifunctional poly(1,3-butadienes) can also be obtained by anionic polymerization.

Hydroxyl-bearing polyacrylates based on 2-hydroxyethyl acrylate or methacrylate monomers are used in the production of high-quality, two-component paints [56] (see also ⟶ Paints and Coatings – Polyurethane Coatings).

Low molecular mass polyols, in contrast to the higher molecular mass polyols mentioned above (Section Polyether Polyols), are used as chain extenders. In the production of PUR elastomers they are generally used in the synthesis of the “hard” segment (see Section Polyurethanes with Segmented Structure). Important representatives are ethylene glycol, 1,4-butanediol, 1,6-hexanediol, and 1,4-bis(hydroxyethoxy)benzene.

Trimethylolpropane or glycerol is added to introduce a defined small degree of branching.

3.3. Diamines and Amino-Terminated Polyethers

Diamines are used as building blocks for PURs that contain urea groups. Due to their high reactivity the polyaddition is very fast even without a catalyst, leading to polymers with considerably improved properties compared with “standard” PURs.

For polyaddition in bulk, sterically hindered diamines (e.g., isomeric diaminodiethylmethylbenzenes **17** [57]) or other aromatic diamines with mono- or dialkyl ring substituents [58-61] are preferred.

17a

17b

These amines are liquid at room temperature and therefore suitable for processing in two-component devices (see Section Metering and Mixing Technology).

Less reactive diamines with electron-withdrawing substituents are used for producing elastomers by the prepolymer process (see Section Prepolymer Processes); examples include bis(4-amino-3-chlorophenyl)methane [101-14-4] (MBOCA) and 2-methylpropyl-4-chloro-3,5-diaminobenzoate [32961-44-7] [62-64]. For the toxicological and adverse health effects of MBOCA, see [65].

Amino-terminated polyethers (ATPE) are obtained primarily from the appropriate polyether polyols (see Section Polyether Polyols) by exchanging the hydroxyl groups with ammonia [66-68] or primary amines [69]. Aminopropoxy end groups are obtained by cyanoethylation of polyols followed by hydrogenation. The high reactivity of the amino groups can be reduced by using their adducts with carbon dioxide (carbonates, carbamates). During the polyaddition reaction the carbon dioxide is released and acts as a blowing agent.

Various processes have been proposed for producing ATPEs with aromatic amine end groups [70]. For example, NCO prepolymers can be hydrolyzed to give the corresponding amino-terminated prepolymers [71]. Other methods include the preparation of N-substituted crotonic acid esters by acetoacetylation of polyols followed by amination [72, 73] and nitrophenylation followed by hydrogenation [74-76].

The adducts of (cyclo-)aliphatic di- and polyamines with ketones are bis- and polyketimines, respectively. They function as capped amines, with which they are in equilibrium in the presence of water (see Section Blocked Isocyanates). In the tautomeric enamine form, they also react with NCO groups to form urea and amides. Combinations of ketimines and isocyanates are thus both moisture- and heat-curing [77-79].

Polyether ketimines based on aliphatic polyether amines have a rather low reactivity and therefore a very good processability [80-83].

3.4. Special Building Blocks

Aqueous PUR-ionomer dispersions are synthesized from diols or diamines that contain ionic groups or groups that can be converted to ionic groups by alkylation or neutralization with compounds such as *N*-methyldiethanolamine, 2-(*N*,*N*-diethylaminomethyl)-2-ethyl-1,3-propanediol, and dimethylolpropionic acid, as well as salts of 2-sulfo-1,4-butanediol, *N*-sulfoethylethylenediamine, *N*-carboxyethylethylenediamine, lysine, and glycerol 2-phosphate [84, 85].

Hydroxy-functional polyisobutylene [86, 87], siliconediamines [88-90], and chlorosulfonated polyolefins [91] can be used as oligomer building blocks leading to segmented PUR polymers.

Other special polyols can be obtained by glycolytic degradation of polymer waste [92-94] (see Section Recycling/Recovery of Polyurethanes).

3.5. Catalysts and Additives

Catalysts. In order to balance the two main reactions, the isocyanate-water reaction (blowing reaction) and the isocyanate-polyol reaction (gel reaction), various catalysts are used. The reactions of the isocyanate group are extraordinarily sensitive to many different kinds of catalysts:

1. Lewis bases: 1,4-diazabicyclo[2.2.2]octane [280-57-9] (DABCO), triethylamine [121-44-8], dimethylbenzylamine [103-83-3], bis[2-(dimethylamino)ethyl] ether [3033-62-3], 1,1,3,3-tetramethylguanidine [80-70-6], 1,8-diazabicyclo[5.4.0]undec-7-ene [6674-22-2] (DBU), 2,4-bis(dimethylaminomethyl)phenol [5424-54-4]
2. Lewis acids: bis(ethylhexanoyloxy)tin [301-10-0] (tin dioctanoate), bis(dodecanoyloxy)dibutyltin [77-58-7] (dibutyltin dilaurate), dichlorodimethyltin [753-73-1]
3. Insertion catalysts: bis(dodecylthio)dibutyltin, organotin alkoxides, organotin oxides, organotin thiolates, organotin sulfides, 1,3-dicarbonyl compounds

Almost every catalyst has a specific “activity profile” [13, 95-99]. The situation is extraordinarily complex, especially since

the urethane group itself exerts a catalytic effect. As hydrogen bonds and the nature of solvents used in the reaction influence the reaction rates, most kinetic studies in solvents are not applicable to solvent-free PUR production [100]. Due to the desire to reduce emanations from PUR foams less volatile or reactive catalysts have been developed [101, 102].

Metal catalysts activate the isocyanate groups by making them more electrophilic, while bases make the hydroxyl groups more nucleophilic [103].

Alkali metal salts of organic acids and phenols, as well as phenol Mannich bases catalyze not only the urethane reaction but also the trimerization of the isocyanate group. NCO prepolymers trimerize more rapidly than the corresponding diisocyanates because of the presence of urethane groups which act as cocatalysts (see Section Polyisocyanurates).

Phosphines are special catalysts which dimerize the NCO group; phospholine oxides cause carbodiimidization.

Additives (see also ⟶ Plastics, Additives).

Foam Stabilizers. Besides the chemical structure and molecular weight of the polyols and isocyanates, cell size and fraction of open cells can be controlled to a certain extent by surfactants or foam stabilizers [104]. In some cases, foam formation is virtually impossible without these surface-active compounds. The majority of foam stabilizers are polysiloxane-polyether block copolymers [105-108]. Specific types, e.g., for liquid CO_2 as blowing agent [109], for flame-retarded foams [110], or for other specific foam types are available as well [111, 112].

Hydrolysis Stabilizers [113-116]. Monocarbodiimides, polycarbodiimides, epoxides, cyanates, phenyliminooxazolidines.

Oxidation Stabilizers [113-115], [117-119]. These additives are used in foamed materials, especially in flexible foams, to prevent core scorching. They include sterically hindered phenols, alkylated anilines, phosphites, hydrazides, sulfides, and thioethers.

UV Stabilizers [113-115, 117-119]. Piperidines with bulky substituents in the 2,6-positions, benzophenones, benzotriazoles, cyanoacetate ester derivatives, quenchers, Tinuvins (Ciba-Geigy).

Blowing Agents (see also ⟶ Foamed Plastics – Blowing Agents). According to the implementation of the Montreal Protocol (and the consecutive amendments) blowing agents with an ozone-depleting potential are no longer used as blowing agents for flexible foam by the member states since 1992. Several alternatives have been developed [120-127].

For flexible foams the predominant technology meanwhile is the addition of liquid or supercritical carbon dioxide (e.g., Novaflex by Hennecke, Cardio by Cannon). Another method is the application of varied ambient pressure, e.g., MegaFoam by Hennecke or VPF by Beamech (see Section Production) and depending on regulations of the local authorities, blowing agents like dichloromethane or acetone may be applied as well.

For rigid foams nowadays usually alkanes, namely, n-pentane, isopentane, and cyclopentane are used (see Section Raw Materials).

Flame Retardants (see also ⟶ Plastics, Additives – Flame Retardants). Various classes of chemicals are used to modify the combustion behavior of PUR flexible foams [128]. The selection of the appropriate flame retardant depends on the test that must be passed, as well as the chemistry of the foam (e.g., polyester vs polyether, HR vs. conventional foam). Most common are phosphorus- and/or nitrogen-containing compounds and halogenated phosphates such as tris(2-chloropropyl) phosphate (TCPP). As in the case of catalysts, less volatile or reactive flame-retardants have been developed in order to reduce the emissions of volatile organic compounds (VOCs) from the finished foam. The liquid flame retardants may be combined with solid ones such as melamine and ammonium polyphosphate. Brominated diphenyl ethers, which have been used for some special foam grades or in some regional markets, will be phased out due to concerns regarding their potential for bioaccumulation.

For rigid foams halogenated compounds such as TCPP, polyesters based on tetrabromophthalic acid, and special bromopolyethers are usually used. The use of polyisocyanurate rigid foams (see Section Special Types), which exhibit a superior flame behavior compared to PUR rigid foams, has increased. This has led to a reduction in flame retardant consumption.

Aluminum oxide trihydrate, magnesium hydroxide, and expandable graphite are also used as flame-retardants. The first two act by splitting off water vapor and the latter acts by forming protective layers.

4. Structure and Morphology

Wolfgang Friederichs

Depending on their structure, PURs cover a broad range of properties. Besides the chemical composition, the chain length, and cross-linking, the properties are significantly affected by the interactions between the polymer chains (see Fig. 1), that is to say by the supramolecular structure and morphology.

Figure 1. Hydrogen bond interactions between polymer chains of a PUR based on HDI and 1,4-butanediol

4.1. Polyurethanes Without Segmented Structure

The properties of linear PURs, which are produced by polyaddition of monomeric diisocyanates and short- or long-chain diols, are similar to those of polyamides.

Short-Chain Polyols. The polyaddition of hexamethylene diisocyanate (HDI) and 1,4-butanediol leads to a very tough, crystalline material (mp 180–185 °C), which is used for manufacturing of fibers and bristles. The polyaddition of toluene diisocyanate (TDI) and butanediol or diethylene glycol yields very hard, transparent products with low heat resistance.

Long-Chain Polyols. Linear PURs based on diisocyanates (preferably MDI) and long-chain polyester or polyether diols are soft, rubbery, high molecular mass polymers with only a small proportion of urethane groups. Therefore, these materials are homogeneous (single phase), and the intermolecular physical interactions are mainly determined by the polyester and polyether segments (van der Waals forces [129]).

With increasing stiffness of the polyol chain (e.g., highly crystalline polyesters), and decreasing chain length, the resulting PUR becomes harder and less elastic.

4.2. Polyurethanes with Segmented Structure

To obtain PUR elastomers with superior properties, the polyaddition reaction mixture usually contains three components, namely, a diisocyanate, a long-chain polyether or polyester polyol, and a short-chain diol (chain extender). The resulting block copolymer type PURs are characterized by a segmented structure.

The secondary and tertiary structures, and as a consequence, the morphology of these PURs, depend on the chemical structure and the block length of the different segments. Due to the two- or multi-phase morphology, segmented PURs can exhibit extraordinary high-grade properties.

4.2.1. *Hard and Soft Segments [12, 130-135]*

The reaction of one equivalent of long-chain diol, one equivalent of short-chain diol, and two equivalents of diisocyanate leads to the idealized structure shown in Figure 2.

The long-chain polyols, which are flexible and are usually tangled (soft segments), alternate along the polymer chain with oligomeric rigid urethane units (hard segments).

Figure 2. Schematic primary structure of a segmented PUR (idealized)

Usually the structure of the PUR as well as the structure of the soft segment itself is determined by a Flory distribution [136, 137]. This results in a smaller number of larger hard segments than expected in theory. If polyester polyols are used, the low molecular glycols, which are usually present in considerable amounts, even enhance this effect. Further effects leading to deviations from theory include kinetic effects (if end groups with different reactivity are used) and phase transitions due to temperature changes during the polyaddition reaction.

4.2.2. *Segregation and Morphology*

On cooling, the initially homogeneous PUR melt converts to a two-phase system. This is due to the incompatibility of the polar low-molecular glycols with the low-polarity polyether or polyester polyols and polyisocyanates. As the reaction progresses, the formation of polar urethane groups at the ends of the long-chain polyols leads to a certain degree of compatibilization. Nevertheless, the low miscibility of the hard and soft segments leads to segregation, which results in covalently bonded microphases in which paracrystalline oligourethane domains appear (tertiary structure, Fig. 3). On further cooling, these can aggregate and grow to form spherulitic microcrystallites (quaternary structure).

Figure 3. A) Tertiary structure of a linear segmented PUR with polydisperse soft segments and uniform (monodisperse) hard segments; B) Cylindrical model of a hard domain

The hard segment domains form three-dimensional cross-linking centers of a noncovalent type (physical cross-linking). The formation of a large number of weak hydrogen bonds results in a high bonding strength, but allows shifts and rearrangements under load, where a covalent bond would rupture. As the hard segments are covalently bonded to the soft segments, flowability of the chains is restricted. This gives the segmented PURs their high elasticity. The hard segments

are responsible for tensile strength, tear resistance, hardness, permanent elongation, and compression set, while the soft segments determine the elastic expansion and the glass transition temperature.

The interaction between different hard segment domains is mainly determined by the symmetry of the isocyanates and the nature of the chain extenders, which influence the possibility to form highly organized structures.

Most commercially produced PURs contain urea groups, which often determine the property profile more strongly than the comparatively small content of urethane groups. Since the urea group is more polar than the urethane group, the segregation of hard and soft segments is strengthened, the melting range of the hard-segment domains is higher, and the intermolecular (interchain) interaction stronger [138]. Due to these strong interactions, a single urea group shows hard-segment character. These interactions also explain the superior mechanical properties of polyureas and their low thermoplasticity.

The balance between these hard segment/hard segment interactions and the interactions between hard segments and soft segments determine the degree of segregation. Due to decreasing polarity, segregation increases from polyesters to polyethers to polybutadiene polyethers.

In the soft segments, strain-induced crystallization can be initiated by stretching or disentanglement. This strain-induced crystallization explains the high hysteresis of typical PUR elastomers [139, 140]. The mechanical properties of segmented PUR depend on the melting temperature of the crystalline domains.

Products based on 1,5-naphthalene diisocyanate (NDI) are no longer thermoplastic because the melting temperature of the hard segments is too high. They are usually produced with a small excess of isocyanate as casting elastomers (see Section Cast Elastomers). These products have extremely good mechanical properties: high tear strength, high abrasion resistance, high elasticity at high hardness, low damping, high load-bearing capacity, and excellent long-term dynamic endurance (load-bearing property) [135].

High-quality PUR thermoplastic elastomers are produced primarily from MDI. The melting temperature and the solubility of these segmented thermoplastic PURs can be influenced by modifying the chemical composition, especially of the hard segments. Use of a second short-chain diol lowers and widens the melting temperature range, and solubility is also improved.

As the properties of segmented PUR are highly determined by the phase segregation and the crystallinity of the domains, numerous production parameters [130, 131, 141-143] have tremendous influence on the behavior of thermoplastic PUR materials. Even thermoplastic PUR with monodisperse (uniform-length) N-alkylurethane hard segments, which are incapable of hydrogen bond formation show differing morphology and properties depending on their thermal pretreatment [144].

4.3. Cross-linking of Polyurethane

PUR flexible and rigid foams, cast elastomers, and most reactive systems are usually cross-linked. Even if these cross-linked PURs are not thermoplastic, the melting of the hard-segment domains is still observable, e.g., by softening (decrease in shear modulus) at elevated temperatures. With increasing cross-linking, the glass transition temperature increases, whereas the tendency to crystallize decreases.

If the cross-linking is not caused by subsequent reactions (formation of allophanate or biuret), but introduced by the use of highly functional raw materials, then the formation of segregated domains can be disturbed due to the rapid formation of a highly cross-linked PUR network, fixing the polymer chains or at least reducing their flexibility. In this case, even heating to elevated temperatures does not improve the material properties, as domain formation is not possible (e.g., in flexible foams).

4.4. Polyisocyanurates [145]

The general term PURs also covers products that contain cyclic urea structures (isocyanurates), which are formed by cyclotrimerization of isocyanate groups. The mechanism of isocyanurate formation is not completely understood. The most probable mechanism of base catalyzed trimerization [146] is shown in Figure 4.

Addition of the catalyst II to the carbon-nitrogen double bond leads to an urethane anion III, which by subsequent addition of two more isocyanate molecules I is transformed via IV to the adduct V. This adduct collapses into the stable isocyanurate VI and regenerates the catalyst II.

Figure 4. Mechanism of base-catalyzed isocyanate trimerization

The isocyanurates exhibit improved mechanical properties such as compression strength and dimensional stability and generally show superior fire retardancy [147]. These advantages have led to the increasing importance of isocyanurates, especially since the blowing agent for rigid foams was switched from CFC to pentane (see Section Special Types).

[Top of Page]

5. Production of Polyurethanes

Wolfgang Friederichs

5.1. Stoichiometry

Isocyanates (RNCO) are specified by their percentage NCO content and in some cases also by their equivalent mass (molecular mass of NCO moiety/functionality). Functionality means the number of isocyanate groups per molecule.

$$\text{Equivalent mass} = \frac{\text{molecular mass of RNCO}}{\text{functionality}} = \frac{42}{\%\text{NCO}} \cdot 100 \tag{1}$$

Polyols are specified by their hydroxyl number (OH no.) and sometimes also by their percentage OH content or their equivalent mass. The OH no. is given in mg KOH/g, owing to the method used for analyzing the OH groups: they are usually treated with acetic anhydride and, after hydrolysis with water, the excess acetic anhydride is titrated with potassium hydroxide. This means that a polyol containing 1 mmol OH groups per gram has an OH no. of 56 mg KOH/g.

$$\text{OH no.} = \%\,\text{OH} \cdot \frac{56 \cdot 1000}{17 \cdot 100} = \%\,\text{OH} \cdot 33 \tag{2}$$

$$\text{Equivalent mass} = \frac{56 \cdot 1000}{\text{OH no.}} \tag{3}$$

Water, *acids* (acid number AN), and secondary and tertiary amines are also most simply characterized by their equivalent mass. For mixed amines, a mean functionality must be used where necessary. For calculating quantities, 1 gram equivalent isocyanate corresponds to 1 gram equivalent Zerewitinoff-active hydrogen compound (e.g., polyol). In practice, the quantity of isocyanate is calculated almost exclusively for 100 parts by weight of the active-hydrogen compound(s). If the raw materials also contain water, then an additional quantity of isocyanate is required, since the latter reacts with water to form carbon dioxide and substituted urea.

The index (or isocyanate index) is equal to 100 (isocyanate index = 1) if the quantity of isocyanate added equals the amount necessary for reaction with all Zerewitinoff-active hydrogen atoms.

$$\text{Index} = \frac{\text{Used isocyanate quantity}}{\text{Necessary isocyanate quantity}} \cdot 100 \tag{4}$$

In practice, the index can be used to influence the properties of the PUR decisively, e.g., by “under-” or “over-cross-linking.” Under-cross-linking means that free hydroxyl groups remain in the PUR; over-cross-linking means that the urethane moieties undergo consecutive reactions, i.e., the formation of allophanates. High indices of 300 or more are used to produce polyisocyanurates (PIR), in which the isocyanate groups undergo trimerization by reaction with each other (see Section Polyisocyanurates).

5.2. Reaction without Solvents

The possibility of manufacturing PURs from liquid raw materials without the use of any solvent is one of the biggest advantages of PUR chemistry. As a result, most PURs are manufactured by a mass polyaddition process. This process can be a single-step reaction (one-shot process) or a two- or multiple-step reaction (prepolymer process). The reactivity is controlled by temperature or by the addition of catalysts. Due to the high exothermicity, reaction temperatures of about 100 to 180 °C are not unusual. These high temperatures guarantee good end curing of the molded PUR parts.

5.2.1. *One-Shot Process*

Bulk reactions without solvents are usually very fast, especially when catalysts are added. Therefore, the production of PUR foams is usually carried out by the one-shot process, in which all components are mixed directly, generally with simultaneous addition of auxiliaries such as catalysts, foam stabilizers, reinforcing agents, fillers, and fire retardants. The reaction is highly exothermic and largely completed in 0.5–30 min, depending upon the catalyst. The final properties, however, are frequently reached only after 24–48 h (post-curing).

The one-shot process requires that the reactivity of all isocyanate species is quite similar. Amines usually lead to excellent PUR properties but react much more rapidly than polyols. If diamines or polyamines are to be used it must be ensured that the urea formed at the beginning of the reaction does not precipitate and is no longer available for incorporation into the hard segments. This means that the use of polyamines is limited to amines which cannot undergo cross-linking (secondary amines), are sterically hindered [57-61, 148], or are deactivated by electron-withdrawing substituents [62-64, 149].

For easy processability all components should be liquid, of low viscosity, and miscible or at least be able to form a homogeneous reaction mixture for the very first moments of the reaction. Usually all the nucleophilic components, that is, polyols and/or polyamines, are premixed and homogenized. If these mixtures are incompatible with the short-chain diols (chain extenders), the miscibility must be enhanced by raising the temperature or adding emulsifiers.

In general, the polyaddition reaction of a multicomponent system by the one-shot process leads to a predominantly statistical structure of the polymer chains.

The term reaction injection molding (RIM) technology usually is used when highly reactive components are mixed and injected into a mold on a very short timescale (see Section Integral Skin Foams and RIM Materials). This technique allows for the handling of reactive systems with pot lives (i.e., the period in which no significant increase in viscosity is observed) of less than 1 s and reaction times of about 10–60 s.

RIM technology has initialized a development, which started with catalyzed highly reactive PUR systems [150], and, by the use of polyurethane-polyurea systems, chain extended by diamines [151-153], led to pure polyurea systems, in which the

only isocyanate-reactive components are diamines [154-163].

5.2.2. *Prepolymer Processes*

In PUR chemistry, prepolymers are defined as intermediate reaction products of the polyaddition reaction which still contain free isocyanate or isocyanate-reactive groups. In contrast to the one-shot process, the prepolymer process allows for a highly controlled polyaddition reaction, e.g., to construct tailor-made segment structures.

In the first step of the process, polyether or polyester polyols are usually treated with excess diisocyanate to yield homogeneous reaction mixtures, which may contain considerable amounts of unconverted isocyanate groups. If diisocyanates with NCO groups of different reactivity are used (2,4-diisocyanatotoluene, isophorone diisocyanate), the resulting NCO prepolymers exhibit narrow molecular weight distribution with only minor amounts of unconverted monomeric diisocyanate.

If prepolymers free of monomeric diisocyanate are required, the latter must be removed, e.g., by thin-film distillation or extraction with a hydrocarbon solvent which does not dissolve the prepolymer. The monomer content is then lowered to below 0.1 % [164, 165].

The production of storage-stable NCO prepolymers from aromatic diisocyanates is difficult and requires special precautions (e.g., the exclusion of all traces of water and catalysts) to avoid side and consecutive reactions [166].

Low-viscosity, monomer-free NCO prepolymers can be obtained from silylated hydroxy compounds and isocyanates with a carboxylic acid chloride group [167, 168].

5.3. Reaction in Solvents

5.3.1. *One-Component Systems*

Linear or slightly branched PURs or polyurethane polyureas with molecular weights of 50 000 to 150 000 g/mol can be obtained by polyaddition reaction in solution. The PURs are usually isolated by evaporation of the solvents or by precipitation, e.g., by pouring the solution into a nonsolvent liquid.

The choice of solvent for the polyaddition is crucial, as the solvent must be able to dissolve both the soft and hard segments of the segmented PUR structure. Polar organic solvents (dimethylformamide, dimethylacetamide, 1-methyl-2-pyrrolidone, sulfolane, etc.) usually fulfill this requirement. In some cases, ketones like acetone or methyl ethyl ketone are also suitable. The ketones are especially suitable for chain extension of NCO prepolymers with aliphatic diamines as they reduce their activity by reversibly forming an adduct.

In industrial processes, linear PURs containing only urethane groups are usually produced without using solvents, but can be dissolved in a solvent if necessary for the application.

PURs containing urethane and urea groups are mainly produced by a two-step process. In the first step a prepolymer is made without the use of any solvents. In the second step this prepolymer is then treated with chain extenders such as diols or diamines. In the second reaction step, the solvent is usually added stepwise to avoid a too rapid increase in the viscosity of the solution. The obtained PUR solutions have PUR contents of ca. 20 to 30 %.

With increasing viscosity it is very difficult to achieve complete conversion of the functional groups. This problem is overcome by using NCO/OH ratios (indexes) slightly above 100 and running the reaction till the viscosity reaches a specified value, which must be determined empirically for each product. Then the reaction is stopped by adding a monofunctional stopper, e.g., dibutylamine.

If the reaction is carried out in highly polar solvents, especially in mixtures of water and acetone, methyl ethyl ketone, or DMF, even highly reactive aliphatic diamines such as ethylenediamine can be used. With increasing molecular mass the products may tend to gelation or precipitation. The solubility of the PUR can be improved by adding small portions of a second chain extender such as 1,2-diaminopropane, piperazine, or water to disturb the formation of the hard-segment domains.

5.3.2. *Two-Component Systems [169]*

Two-component systems are of tremendous importance for coatings and for leather and paper finishing. They usually consist of a polyhydroxy compound and an isocyanate cross-linker.

The polyhydroxy compounds are usually obtained by chain extension of common polyether or polyester polyols with diisocyanates; the isocyanate cross-linkers, which for ecological reasons must be free of isocyanate monomers, may be

NCO prepolymers made by the reaction of diisocyanates with diols, diamines, or water; or they may be modified isocyanates, e.g., trimerization products of HDI (see Section Aliphatic Polyisocyanates).

To increase the amount of reactive components in the solvent-containing two-component systems, numerous improvements have been introduced to industrial processes: part of the solvent can be substituted by reactive thinners [170], which are incorporated into the cross-linked PUR. By using new catalysts an unsymmetrical trimerization product of HDI [30], with particularly low viscosity, has been developed, allowing for higher concentrations (high-solids systems) without deterioration in the processability.

5.4. Reactive One-Pack Systems

The term “one-pack system” denotes the storage-stable, ready-to-use formulation of a polymer precursor which cures without addition of further components, e.g., curing agents. Curing generally is caused by humidity, atmospheric oxygen (mainly used in paints), or by the thermal elimination of a blocking agent (see Section Blocked Isocyanates), which either vaporizes or remains in the cured polymer.

Other curing systems involve encapsulated materials with a diffusion barrier layer, which is broken, e.g., on heating. They cure without uptake or release of a substance.

Moisture Curing. Relatively low molecular mass NCO prepolymers can be dissolved in small amounts of low-polarity solvents (e.g., 75 % solution in ethyl acetate) and cured by the action of atmospheric moisture. The curing rate depends on the atmospheric humidity and temperature. Usually these solutions are used as paints or coatings, and the carbon dioxide formed as a byproduct escapes from the thin film without bubble formation.

Eliminating Blocking Agents. Mixtures of blocked NCO prepolymers with polyols are stable at storage temperatures (20–50 °C) and are cured by heating (> 120 °C) to eliminate the blocking agent (see Section Blocked Isocyanates). The reaction can be conducted in such a way that an isocyanate intermediate does not appear [39]. Appropriate hydrophilic modification can be used to produce such combinations as low-viscosity aqueous emulsions or dispersions, in which one of the components usually has a high molecular mass [38].

Removal of a Diffusion Barrier Layer. Some solid diisocyanates such as NDI, TDI-urea, and TDI-uretdione (TDI-dimer) can be stabilized by encapsulation with a diffusion barrier layer. The barrier layer is produced by dispersing the solid isocyanate in a solvent and reacting the NCO groups at the particle surface with (cyclo-)aliphatic diamines. After removal of the solvent the encapsulated isocyanates are dispersed in polyols or polyamines.

Liquid, pasty, or granular one-pack systems are produced in this way. They can be stored for several months and are made to react by heat shock, e.g., 1 min at 120 °C. Heat-curable reactive powders can also be produced on this basis [171].

5.5. Other Processes

In addition to the industrial isocyanate polyaddition processes described previously and in subsequent sections, several other synthetic methods for PURs or polyureas are of scientific interest [172].

PURs can also be obtained by the polycondensation reaction of bis-chloroformate esters and diamines. This method has the advantage over the polyaddition method that it can be carried out under very mild conditions (at ≤20 °C).

If secondary diamines such as piperazine are used in the polycondensation reaction, thermostable poly(N-alkylurethanes) are obtained. This principle has been used to produce, e.g., high-melting PURs [173] for fibers or PURs with liquid-crystalline character [174]. Liquid-crystalline PURs have also been produced from *N*-alkylcarbamic acid chlorides and diols.

Another method for preparing PURs is the ring-opening polyaddition of oligomers with cyclic ethylene carbonate groups and di- or polyamines, which leads to segmented PURs with free hydroxyl groups [175, 176]:

Functionalized PURs can be obtained if carbonylbiscaprolactone (CBC) is used as carbonyl source [177]. Due to its high

selectivity, reactions with diamines can be carried out even in the presence of additional hydroxyl groups.

High-molecular mass α, ω-bis(amino) prepolymers for use in RIM technology (see Section Integral Skin Foams and RIM Materials) have been produced by the reaction of α, ω-bis(amino)polyethers with urea [178].

6. Processing of Polyurethanes

Udo Maier

6.1. Supply, Storage, and Preparation of Raw Materials

The raw materials are transported in small (< 100 kg) and normal-sized drums (200–250 kg), and (road) tank trucks and trailers (ca. 23 t). The regulations applicable to the transportation of chemicals (including labeling) must be observed, as well as the transportation conditions prescribed by the manufacturer for preserving the quality of the raw materials. If raw materials are delivered by tank truck, storage tanks for polyol and isocyanate should be installed in pairs at the processing site (Fig. 5). The size of the storage tanks should be adapted to the delivery volume (frequently 15 or 30 m^3). Since the raw materials in the tank truck are usually delivered at elevated temperature, they must be cooled to the processing temperature (22–25 °C) in the storage tank. Ordinary thick plate can be used as the tank material.

Figure 5. Tank truck unloading and storage tanks

6.2. Metering and Mixing Technology

In contrast to the machines used for processing thermoplastics, which consist of devices for melting, molding, and solidifying, the machines used for producing PUR moldings or semifinished parts contain all the elements of a chemical reactor.

The raw materials are conveyed from the storage tank, optionally via premixing stations for adding auxiliary materials, to the processing machine. Often the metering and mixing machine is called the wet part of the processing plant. Figure 6 schematically depicts a two-component metering and mixing machine with an impingement mixer as the mixing unit. In practice, machines using the impingement mixing principle are available for mixing up to six components. In the working tanks (a), the raw materials are prepared for processing, i.e., primarily their temperatures are adjusted precisely. Any temperature change, especially of the polyols, results in a viscosity change, which can impair later processing. The working tanks (volume 20–500 L according to the machine size) are therefore usually provided with heating and cooling jackets. Separate temperature-control circuits via heat exchangers are also common. The working tank is also equipped with an agitator for homogenization as well as an automatic refilling system and indicators for level, pressure and temperature. The conditioned raw materials are conveyed via metering pumps (b) to the most important part of the machine, the mixing head (c), which delivers the liquid reaction mixture.

Figure 6. Principle of a high-pressure machine (circulation system)

a) Working tank; b) Metering pump; c) Mixing head; d) Safety valve; e) Filter; f) Hydraulic unit

Depending on the PUR system to be processed, precision metering pumps of various outputs (up to 150 L/min) and pressure ranges (up to 250 bar) are used. The pumps must always satisfy extremely high requirements for metering accuracy in order to maintain a certain reaction mixture. In addition to conventional gear pumps and in-line piston pumps, which have been established in PUR technology for many years, axial piston pumps (Fig. 7) and, for systems containing fillers and reinforcements, slow-running single-cylinder positive-displacement pumps are used (Fig. 8).

Figure 7. Axial piston pump

feeding side; g) Stop valve: delivery side

Two types of mixing principles exist: low-pressure mixing heads with an agitator (3–40 bar) and high-pressure mixing heads (100–250 bar). In mixing heads with an agitator, the raw materials entering the upper part of the mixing chamber are intensively mixed on their way to the outlet by rotating, variable-speed agitators. Agitators include spiked, paddle, or screw agitators, propellers, or turbine impellers. After the end of the shot the agitators are cleaned with a rinsing medium. High-pressure mixing heads operate according to the countercurrent injection principle. The component streams are injected into the mixing chamber via nozzles (Fig. 9) and are mixed by virtue of the kinetic energy used and the chaotic flow behavior created [179].

Figure 9. View into an impingement mixer during shot; visualization of streamlines

In controlled-circulation mixing heads, the raw material streams are changed from the “circulation position” (Fig. 10A) (tank ⟶ pump ⟶ mixing head ⟶ tank) to the “injection position” (Fig. 10 B). After injection has occurred, a piston cleans the remaining reaction mixture from the mixing chamber and outlet pipe. These are therefore known as self-cleaning mixing heads.

Figure 10. Circulating-groove mixing head

A) Circulation/cleaning; B) Mixing

a) Nozzle; b) Piston; c) Groove; d) Outlet tube

So-called L-shaped mixing heads are able to improve the homogeneity of the reaction mixture by a perpendicular deflection of the flow direction and simultaneous acceleration of the flow velocity (Fig. 11). Furthermore, the larger diameter of outlet tube compared with the dimension of the mixing tube allows the required laminar flow out of the mixing head.

6.3. Processing Plants

A two- or multicomponent metering and mixing machine is part of each processing plant. Further equipment and machines define the kind of processing plant.

In continuous plants, semifinished products are produced in the form of blocks, slabs, boards, profiles, etc. The scheme in Figure 12 depicts a plant for the continuous production of foam slabs. Four components are metered, mixed with an agitator mixing head, and poured onto the conveyor belt. The bottom and side paper are used to keep the conveyor belt clean and to avoid sticking of the foam to the conveyor belt during rising and curing. Figure 13 is a three-dimensional view of a plant for the manufacture of rectangular slab stocks.

A three-dimensional drawing of a plant for manufacturing metal sandwich panels (Fig. 14) gives an impression of how large and complex PUR plants can be. The length over all stations of processing steps in this case is ca. 350 m.

Plants for producing moldings operate batchwise. The example in Figure 15 shows a top view of a processing plant: On the left side is the wet part of the plant with a total of six components; a robot handles the high-pressure mixing head, and two clamping units are available for pouring into open moulds.

Figure 15. Layout of a plant for producing moldings by open-mold filling technology

a) Tank unit; b) Pump unit; c) Robot with mixing head; d) Clamping units; e) Protective guard

A distinction can be made between plants with movable (Fig. 16) and those with stationary molds (Fig. 17). Movable molds are supplied by a single mixing head, whereas in RIM plants, several mixing heads are used, each of them being permanently assigned to one (stationary) mold. The plants are preferably automatically controlled with electronic equipment.

7. Foams

Norbert Adam, Geza Avar, Sven Meyer-Ahrens

Whilst the reaction of isocyanates with water in most PUR applications is an unwanted side reaction, for foams this reaction is of utmost importance, due to the two reaction products formed. These are CO_2, which acts as the blowing agent for foam formation, and the more or less crystalline polyurea domains, which control cell opening and act as reinforcing filler in the PUR backbone. This chemical blowing process was supplemented in the early 1960s by a physical

blowing process using low-boiling liquids as blowing agents. These liquids are vaporized by the heat of reaction of the polyaddition reaction between isocyanates and polyols and/or water. The blowing agent vapor is trapped in the viscous reaction mixture and thus leads to the cellular structure of the foam. Since foam formation is a very sensitive and complex process of interdependent chemical, physical, and rheological processes, specific additives and catalysts are required (see Section Catalysts and Additives).

PUR foams are generally divided into flexible, rigid, and semiflexible products. Integral skin foams, which have a densified surface layer forming an elastomerlike skin and a foamed core, are described in Section Integral Skin Foams and RIM Materials .

Polyols with a relatively high molecular mass (2000–8000 g/mol) and a nominal functionality of 2–6 yield flexible foams. Combinations of these polyols with low molecular mass glycols or amines as chain extenders and preferably polyisocyanates with a functionality of more than two yield semiflexible foams. Highly branched polyols, e.g., polyethers based on sorbitol or sucrose, with a relatively low molecular mass (<1000 g/mol) are the basis of rigid foams.

For all these classes of foams different types of manufacturing processes may be applied. An alternative way of classifying foams is therefore based upon the manufacturing process.

Depending on the processing, a distinction is made between molded foam and slabstock foam. Besides these most prominent groups of flexible foams, other foam types include cavity-filling foam (e.g., filling of cavities in car bodies for acoustical or reinforcing purposes) and spray foam (e.g., for thermal insulation of roofs). The term “filling foam” essentially refers to semiflexible foams behind appropriate overlays, e.g., flexible plastic sheets, films, etc.

7.1. Flexible Foams

Most flexible foams are produced continuously as slabs or batchwise by molding. They are characterized by reversible deformability and an open-cell structure, associated with air permeability.

7.1.1. *Flexible Slabstock Foam*

7.1.1.1. *Raw Materials*

Based on different chemistries on the polyol side, three fundamentally different types of slabstock have to be considered: Polyester foams, made from polyester polyols, conventional polyether foam, made from polyether polyols with mainly secondary OH groups and high-resilient (HR) foamf, made from polyether foams with mainly primary OH groups.

The isocyanate used for polyester foams is usually TDI 65 (see Section Aromatic Polyisocyanates) or blends of TDI 65 and TDI 80; the typical isocyanate for polyether foams is TDI 80. High-resilient slab stock foam is produced from polyethers and TDI 80, both optionally modified.

Main components (parts by weight) of a formulation for flexible polyester foam:

Polyester polyol (OH no. 65), e.g., Desmophen 2200	100
TDI 65 and/or TDI 80, e.g., Desmodur T65, Desmodur T80	variable
Index	95
Water	2.5–4.8
Amine catalyst	0.3–0.6
Foam stabilizer	0.7–1.3

Main components (parts by weight) of a formulation for flexible polyether foam:

Polyether polyol (OH no. 48), e.g., Arcol 1108	100
TDI 80, e.g., Desmodur T80	variable
Index	98–115
Water	2.0–4.5
Amine catalyst	0.15
Tin dioctanoate	0.12–0.28
Foam stabilizer	0.6–1.5

Main components (parts by weight) of a formulation for high-resilient (HR) flexible foam:

Grafted polyol (OH no. 28), e.g., Desmophen 7653	100
TDI 80, e.g., Desmodur T80	variable
Index factor	95–113
Water	1.5–4.0
Amine catalyst	0.10–0.20
Diethanolamine	0.8–1.5

Tin dioctanoate	0.1–0.35
Foam stabilizer	0.3–1.0

The polyesters (M_r 2000–3000 g/mol) are usually based on adipic acid and linear glycols (e.g., diethylene glycol), or triols (glycerol or trimethylolpropane) if slight branching is desired.

The polyethers used (M_r 1000–6000 g/mol) are di- and/or triols with a varying propylene oxide/ethylene oxide ratio, which is tailored to the foam's application. An important factor for polyether foaming is a well-balanced ratio of the metal and amine catalysts, which controls the simultaneous reactions of the NCO group with hydroxyl groups (polyurethane reaction) and with water (blowing reaction). If the polyurethane reaction rate predominates, the foam may shrink due to the formation of a high proportion of closed cells. If the water reaction proceeds too rapidly, the carbon dioxide formed cannot be contained in the cells; splits result and the foam can even collapse.

High-resilient foams are produced from highly reactive grafted polyethers which contain a high proportion of primary OH groups (from ethylene oxide). Grafting is achieved by in situ polymerization of styrene and acrylonitrile to form a stable SAN suspension in the polyol. Another class of grafted polyols is based on the polyaddition of TDI and hydrazine to yield PHD polyols which contain suspended polyhydrazodicarbonamide/polyurea particles. If highly functional (pre-cross-linked) modified TDI types are used, unmodified polyols can be applied, but due to advantages in foam processing, this approach has been generally replaced by grafted-polyol technology.

7.1.1.2. *Production*

The raw materials are processed in fully continuous plants to give flexible foam slabs up to 220 cm wide, 120 cm high, and of any length. Depending on the slab dimensions, internal temperatures of up to 165 °C are reached as a result of the exothermic reaction. This temperature must not be exceeded, otherwise severe scorching and even self-ignition of open-celled foam may occur. The foaming process is completed after ca. 3 min, and final curing takes from about 10–12 h up to 72 h, depending on the foam type. The slabs are therefore stored in curing storage facilities until they have cooled and attained their final mechanical properties, so that they can be transferred to further processing, fabrication, etc. The length of the slabs varies from 10 m (short slabs) to 120 m (long slabs). To minimize trimming losses of the foam buns, which would be dome-shaped under free-rise conditions, various technologies are applied to produce rectangular slabs.

Figure 18 shows the principle of a rectangular slabstock plant (Hennecke Planibloc process) [180]. A cover is applied to the rising foam. The pressure of the skids avoids the development of the usual slab dome without the foam becoming compacted. Besides a rectangular slab cross section, this process gives an increased yield of foam due to partial foaming of the mixture at the slab surface, which would otherwise form the surface skin.

Figure 18. Principle of a plant for production of rectangular flexible foam slab stocks

a) Covering paper; b) Skids; c) Mixing head; d) Conveyor belt; e) Foam

In other processes a polyethylene film is drawn up to the slab sides in synchronization with the rising movement of the foam (Draka-Petzetakis) [181, 182]; or the reaction mixture is discharged into a trough with a sloping bottom, in which it rises and then flows off over a downward incline (fall plates) onto the conveyor (Maxfoam) [183]. A more recent development (Multiflex, Quadrofoamat, see Fig. 13) combines the fall plates with liquid laydown principles.

The application of reduced air pressure during the foaming process (variable-pressure foaming, Beamech [184]) or the introduction of carbon dioxide into the mixing chamber (e.g., Multistream (Fig. 19) and Novaflex (Fig. 20), Hennecke [185]) has allowed for the complete elimination of other physical blowing agents such as CFCs.

Figure 19. Multistream (Hennecke)

Figure 20. Novaflex creamer (Hennecke)

Rectangular blocks can also simply be produced batchwise by introducing the reaction mixture into metal or wooden boxes and at a given time putting a floating cover on the rising foam. In addition to primitive methods (“box foam”), mechanized box processes are also offered for this purpose with relatively low investment costs and a processing capacity of up to 1000 t/a (e.g., Hennecke Bloc-Foamat BFM 100). Special versions of these batch plants are available so that different ambient pressures can be applied during the foaming stage (e.g., Hennecke Megafoam).

In addition to the production of blocks with a rectangular cross-section, continuously produced blocks with a round cross section (diameter ca. 120 cm) have become industrially important (Reeves Brothers, General Foam [186, 187]). These buns can be peeled seamlessly.

7.1.1.3. *Properties*

The mechanical properties of the foam are largely determined by the raw materials and the formulation used and by its apparent density. For flexible foam slabstocks, the usual densities are 20–40 kg/m^3, but extremely light and extremely heavy types of foam (from 16 kg/m^3 and up to 130 kg/m^3) can be produced industrially for special fields. The choice of density is determined by the specific application of the foam: the higher the density, the better the properties or the lower the fatigue of the foam when in continuous use.

The hardness (measured as compressive strength at 40 % compression) is an important characteristic of PUR foams (Table 4). The hardness can be varied within wide limits by altering the formulation. Considerably softer conventional foams are obtained, e.g., by including polyethers of high ethylene oxide content and special additives. Hardness control is also possible through the index or the addition of grafted polyols.

Table 4. Relation between apparent density and compressive strength of various grades of flexible foam slab stock

Flexible foam system	Apparent density (ISO 845), kg/m^3	Compressive strength at 40 % compression (ISO 3386), kPa
Polyester foam, based on Desmophen 2200B/Desmodur T65	35	6.5
Polyether foam, based on Polyether 10WF15/Desmodur T80/T65	36	6.0
Polyether foam, based on Arcol 1108/Desmodur T80	36	4.5
HR slab stock foam, based on Desmophen 7619W /Desmodur T80	34	2.7

Apart from the hardness, other characteristic values can be derived from the hysteresis loop (Fig. 21). The slope of the loading curve and the area enclosed by the loading and unloading curves (hysteresis) are measures of the elasticity and energy absorption of the foam: the closer the curves are together, the more elastic the foam; and the larger the area, the better the energy absorption or damping properties of the foam. HR slabstock foam has the best elasticity, followed by polyether foam and polyester foam.

Figure 21. Hysteresis loops of different grades of flexible foam slab stock (apparent density 35 kg/m^3)

a) Loading lines; b) Unloading lines

— Polyester-based foam; – – – Polyether-based foam; – · – · – HR foam

Some important mechanical properties are summarized in Table 5 to demonstrate their range of values. Table 6 shows the values for fatigue in continuous use under the conditions of short-duration tests.

Table 5. Mechanical properties of various grades of flexible foam slabstock

Flexible foam system	Tensile strength (ISO 1798), kPa	Elongation at break (ISO 1798), %	Compressive set (after 90% deformation; ISO 1856), %
Polyester foams	160 – 220	100 – 400	5 – 15
Polyether foams	100 – 180	100 – 400	2 – 10
HR slabstock foams	50 – 120	80 – 200	2 – 10

Table 6. Change of hardness on ageing of various grades of flexible foam slab stock

Flexible	Apparent density	Decrease of indentation	Decrease of compressive

foam system	(ISO 845), kg/m^3	load deflection (ISO 3385), %	strength (5 d , 90°C, 95% rel. hum.), %
Polyester foams	25	43	35
	35	29	40
	45	26	40
Polyether foams	20	34	10
	25	29	14
	35	19	18
	50	16	16
HR slabstock foams	25	24	8
	35	18	13
	45	16	18

The following list contains some additional properties of flexible PUR slabstock foams:

Thermal conductivity: 0.033–0.040 W m^{-1} K^{-1} (at 0–70 °C and densities of 20–70 kg/m^3)

Temperature stability: from –40 to +80 °C without embrittlement.

Open-cell character (see also reticulation capability): 98–100 % with respect to air permeability, not with respect to resistance to air flow.

Chemical resistance to acids and alkalis: polyether foam has a better resistance to acids and alkalis than polyester foam.

Chemical resistance to organic solvents: polyester foam shows a better resistance to organic solvents than polyether foam.

Chemical resistance to atmospheric oxygen: oxygen attacks foam slab stocks only superficially without harming the serviceability. Polyether foam is more easily oxidized than polyester foam. However, if aromatic polyisocyanates and polyether polyols are used for foam production, the foam will decompose over time if exposed to oxygen and light.

Combustibility (see Section Fire Performance of Polyurethanes): Flexible slabstock PURs are combustible, like all organic (carbon-containing) materials. By addition of suitable flame retardants the combustion behavior of foams can be adjusted to meet several flammability standards such as MVSS 302, BS 5852 part 2 Crib V, or even Fire Class B1 (DIN 4102). Also a post-treatment with latices containing flame retardants is possible, in particular if demanding tests have to be met. Besides flame retardants, the type of foam (polyester, conventional, or high resilient) is important if certain flammability standards have to be met.

Bactericidal and fungicidal treatment is possible by including appropriate additives in the formulation or by post-treatment.

Reticulation capability (see also open-cell character): the flow resistance can be greatly reduced by using chemical or physical processes (Chemotronics) to remove residual cell membranes (filter foams).

Physiological aspects: According to extensive studies (both dermatological and oral toxicity in animals), flexible PUR foam of defined composition is physiologically harmless.

7.1.1.4. *Trimming and Processing*

Various possibilities and machines are available for processing the cured slabstock foam to finished articles. The simplest processes for foam blanks are horizontal-cutting (e.g., long-block cutting/peeling), vertical cutting, and angular cutting. These are carried out with continuously rotating knives.

Profile cutting in the form of copy cutting and punching, compression cutting, and milling is used for further forming. With profile cutting tailor-made cuts can be made by following prefabricated templates or drawings (Fig. 22).

Figure 22. Cutting methods and punching

A) Hot-wire cutting; B) Copy cutting; C) Profile cutting; D) Punching

Compression-cutting is a special variant of profile-cutting. All these processes exploit the easy deformability and excellent recovery of PUR flexible foam (Fig. 23).

Figure 23. Compression cutting

A) Convoluting process; B) Skiving process
